

### THAT 2151, 2150A, 2155

#### FEATURES

- Wide Dynamic Range: >116 dB
- Wide Gain Range: >130 dB
- Exponential (dB) Gain Control
- Low Distortion: (0.008% @ 0 dB gain, 0.035% @15dB gain)
- Wide Gain-Bandwidth: 6 MHz
- Low Cost: \$2.20 in '000s (2155)
- Single In-Line Package
- Dual Gain-Control Ports (pos/neg)

#### APPLICATIONS

- Faders
- Panners
- Compressors
- Expanders
- Equalizers
- Filters
- Oscillators
- Automation Systems

#### Description

The THAT 2150 Series integrated-circuit voltage-controlled amplifiers (VCAs) are high-performance current-in/current-out devices with two opposing-polarity, voltage-sensitive control ports. Based on dbx technology, they offer wide-range exponential control of gain and attenuation with low signal distortion. The parts are housed in a space-efficient, plastic 8-pin single-in-line (SIP) package, and re-

quire minimal support circuitry. Fabricated in a super low-noise process utilizing high  $h_{FE}$ , complementary NPN/PNP pairs, the 2150 Series VCAs combine high gain-bandwidth product with low noise, low distortion, and low offset to offer discrete performance at IC prices. They are available in three grades, selected for distortion, allowing the user to optimize cost vs. performance.

Figure 3. Typical Application Circuit

Figure 4. Frequency Response Vs. Gain (2150A)

Figure 5. Noise (20kHz NBW) Vs. Gain (2150A)

$$A_v = 10^{\frac{-E_c}{0.122}}$$

When pin 3 is at 0 V, the current ratio is unity. When pin 3 is at +122 mV, the output current (Q4) is 10 times (20 dB) less than the input current. At -122 mV, the output current is 10 times (20 dB) greater than the input current. Another way of expressing this relationship is:

$$\text{Gain} = \frac{-E_c}{0.0061}, \text{ where Gain is the gain in decibels.}$$

### Negative Input Currents

For negative input currents, Q1/D1 operate with Q2/D2 to mirror the lower-half-core behavior. Pin 2 is normally at or very near ground (see the section below on *Symmetry Adjustment* for more detail), so the same gain scaling applied to the base of Q3 is applied to the base of Q2. The polarity (positive/negative, in dB) of the gain is the same for the top pair versus the bottom pair of the four "core" transistors because their sexes (NPN/PNP) are inverted in the top versus the bottom, while the bases are cross-connected between the input (left) half and the output (right) half of each pair.

The resulting control over gain is extremely consistent from unit to unit, since it derives from the physics of semiconductors. Figure 7 shows actual data from a typical 2150 Series VCA, taken at 25°C.

Figure 7. Gain Versus Control Voltage (Pin 3) at 25°C

### Core Bias Currents

A quiescent bias current in the core transistors is established by the *Voltage Bias Generator* shown in Figure 6. This current acts like crossover bias in the output stage of a complementary class AB power amplifier, smoothing the transition between turning on the top (PNP) pair and the bottom (NPN) pair of transistors in the core. This lowers distortion greatly at some cost to noise performance, as the current noise of the core transistors (which run at approximately 20 μA) is the dominant noise source in the 2150 Series VCAs.

### Transistor Matching

The bias current flows downwards in the core (from Q1 to Q3, and from Q2 to Q4) so long as there is good matching between all four compound transistors (transistors plus diodes). Mismatches will cause a dc output current to flow in pin 8, which will ultimately manifest itself as a dc offset voltage. Static offsets are of little consequence in most audio applications, but any mismatch-caused dc output current will be modulated by gain commands, and may become audible as "thumps" if large, fast gain changes are commanded in the presence of significant mismatches.

Transistor matching also affects distortion. If the top half of the gain cell is perfectly matched, while the bottom half is slightly off, then the gain commanded by the voltage at pin 3 will affect the two halves of the core differently. Since positive and negative halves of ac input signals are handled by separate parts of the core, this gives rise to even-order distortion products.

### Symmetry Adjustment

The monolithic construction of the devices assures relatively good matching between the paired transistors, but even small  $V_{BE}$  mismatches can cause unacceptable asymmetries in the output. For this reason, the bases of Q1 and Q4 are brought out separately to pin 2 and pin 4, respectively. This allows a small static voltage differential to be applied to the two bases. The applied voltage must be set to equal the sum of the  $V_{BE}$  mismatches around the core (*which varies from sample to sample*). Figure 3 (Page 3) includes a typical circuit to apply this symmetry voltage.  $R_{SYM}$  controls primarily even-order harmonic distortion, and is usually adjusted for minimum THD at the output. Figure 8 plots THD vs. the voltage between pins 2 and 4 (the two  $E_{C+}$  ports) for various gain settings of a typical part.

### Opposite Polarity Control

As may be seen from the mathematics, the bases of Q1 and Q4 can also be used as an additional control

Figure 8. Typical THD Versus Symmetry Voltage

port, with an opposite sense of control from that at pin 3. To use this port, *both* pins must be driven with the control voltage, while a small differential voltage is accommodated between the two pins. (Figure 14, Page 9, shows the typical connection.) Either pin 3, or pins 2 and 4, or both ports together may be used for gain control. Mathematically, this relationship is as follows:

$$A_V = 10^{\frac{E_{C+} - E_{C-}}{0.122}}, \text{ where } A_V \text{ is the gain in volts/volt, or}$$

$$\text{Gain} = \frac{E_{C+} - E_{C-}}{0.0061}, \text{ where Gain is the gain in decibels.}$$

### Control Port Source Impedance

The control ports (pins 2 through 4) are connected directly to the bases of the logging and/or antilogging transistors. As was implied in the earlier discussion on *Logging and Antilogging* (Page 4) the accuracy of the logging and antilogging is dependent on the  $E_{C+}$  and  $E_{C-}$  voltages being exactly as desired to control gain. The base current in the transistors will follow the collector currents, of course. Since the collector currents are signal-related, the base currents will also be signal-related. Should the source impedance of the control voltage(s) be large, the signal-related base currents will cause signal-related voltages to appear at the control ports, which will interfere with precise logging and antilogging, in turn causing distortion.

The 2150 Series VCAs are designed to be operated with zero source impedance at pins 2 and 3, and a  $50\Omega$  source impedance at pin 4. (Pin 4 is intended for connection to the symmetry control, hence the higher design-center source impedance.) One can estimate the distortion caused by a specific, non-zero source impedance by determining the base voltage modulation due to signal current based on a core-transistor  $\beta$  of approximately 300 (NPN) or 100 (PNP), and converting the resulting decibel gain modulation to a percentage. Even  $100\Omega$  can spoil the good performance of these parts at high signal levels.

### DC Input Signals

Any dc currents in the feedback loop of the internal op amp will show up as dc terms in the output signal, and will be modulated by gain commands. Input bias currents will cause a dc current to flow in the feedback loop provided by the input side of the core. For this reason, input bias currents in the internal op amp must be kept very low. The bias current compensation at the input stage provides excellent cancellation of the bias current required by the input differential amplifier. Of course, this good performance can be negated by a dc current supplied from outside the VCA. To pre-

vent such dc terms, ac input coupling is strongly recommended. A plot of typical output offset voltage versus gain for the circuit of Figure 3 is shown in Figure 9. (The LF351's offset was adjusted to 0 V for this plot.)

Figure 9. DC Offset Vs. Gain, After Symmetry Adjustment

### Current Programming

The size of the current source at the bottom of the core (Figure 6, Page 4) is programmed externally via  $I_{SET}$ , which is normally determined by a resistor from pin 5 to  $V_-$ . The voltage at pin 5 is typically  $-2.7$  V.  $I_{SET}$  divides into two portions: approximately  $400\mu\text{A}$  is used for internal biasing, and the rest is available for the current source at the bottom of the core.  $I_{SET}$  should therefore be  $400\mu\text{A}$  larger than the total of the peak input and output signal currents.

Note that the output impedance of the internal op-amp is approximately  $2\text{ k}\Omega$ , and under peak demands, the sum of the input and output currents plus  $I_{SET}$  must be supplied through this impedance, lowering the voltage available to drive the core. For more information, see the *Power Supplies* section on Page 8.

### Headroom

Maximum signal currents are also limited by the logarithmic characteristics of the core transistors. In the 2150 Series, these devices are specially constructed to conform to an ideal log-linear curve over a wide range of currents, but they reach their limit at approximately  $1\text{ mA}$ . The symptom of failing log conformance is increasing distortion with increasing current levels. The onset of distortion is gradual at low current levels, and then more rapid as current becomes high. Figures 10 through 12 show distortion versus signal level for the three parts in the 2150 Series for  $-15\text{ dB}$ ,  $0\text{ dB}$ , and  $+15\text{ dB}$  gain. The acceptable distortion will determine the maximum signal level for a particular design.

Figure 12. 1kHz THD+Noise Vs. Input, +15 dB Gain

## Applications

### Input

As mentioned above, input and output signals are currents, not voltages. While this often causes some conceptual difficulty for designers first exposed to this convention, the current input/output mode provides great flexibility in application.

The input pin (pin 1) is a virtual ground with negative feedback provided internally (see Figure 6, Page 4). The input resistor (shown as 20 k $\Omega$  in Figure 3, Page 3) should be scaled to convert the available ac input voltage to a current within the linear range of the device. (Peak input currents should be kept under 1 mA for best distortion performance.) An additional consideration is stability: the internal op amp is intended for operation with source impedances of less than 30 k $\Omega$  at high frequencies. For most audio applications, this will present no problem.

The choice of input resistor has an additional, subtle effect on distortion. Since the feedback impedances around the internal opamp (essentially Q1/D1 and Q3/D3) are fixed, low values for the input resistor will require more closed-loop gain from the opamp. Since

the open-loop gain naturally falls off at high frequencies, asking for too much gain will lead to increased high-frequency distortion. For best results, this resistor should be kept to 10 k $\Omega$  or above. Distortion vs. frequency for a 1 V signal at 0 dB gain with a 20 k $\Omega$  input resistor is plotted in Figure 13.

The quiescent dc voltage level at the input is approximately +10 mV. As mentioned above, any dc input currents will cause dc signals in the output which will be modulated by gain, causing audible thump. There-

Figure 13. THD Vs. Frequency, 0 dB Gain

fore, capacitive coupling is almost mandatory for quality audio applications. Choose a capacitor which will give acceptable low frequency performance for the application.

Multiple signals may be summed by multiple resistors, just as with an inverting op amp configuration. In such a case, a single coupling capacitor may be located next to pin 1 rather than multiple capacitors at the driven ends of the summing resistors. However, take care that the capacitor does not act as an antenna for stray signals.

## Output

The output pin (pin 8) is intended to be connected to a virtual ground node, so that current flowing in it may be converted to a voltage (see Figures 3, 14, & 15). Choose the external op amp for good audio performance. The feedback resistor should be chosen based on the desired current-to-voltage conversion constant. Since the input resistor determines the voltage-to-current conversion at the input, the familiar ratio of  $R_f/R_i$  for an inverting op amp will determine the overall voltage gain when the VCA IC is set for 0 dB current gain. Since the VCA performs best at settings near unity gain, use the input and feedback resistors to provide design-center gain or loss, if necessary.

A small feedback capacitor around the output op amp is necessary to cancel the output capacitance of the VCA. Without it, this capacitance will destabilize most op amps. The capacitance at pin 8 is typically 30 pf.

## Power Supplies

The positive supply is connected directly to pin 7. No special bypassing is necessary, but it is good practice to include a small (~1  $\mu$ f) electrolytic close to the VCA IC on the PCB. Performance is not particularly dependent on supply voltage. The lowest permissible supply voltage is determined by the sum of the input and output currents plus  $I_{SET}$ , which must be supplied through the resistor at the top of the core transistors (see Figure 1) while still allowing enough voltage swing to bias the internal op amp and the core transistors themselves. This resistor is approximately 2 k $\Omega$ . Reducing signal currents may help accommodate low supply voltages.

The highest permissible supply voltage is fixed by the process characteristics and internal power consumption. +15 V is the nominal limit.

The negative supply terminal is intended to be connected to a resistive current source, which determines the current available for the core. As mentioned before,

this source must supply the sum of the input and output signal currents, plus the bias to run the rest of the IC. The minimum value for this current is 430  $\mu$ A over the sum of the required signal currents. 2.4 mA is recommended for most pro audio applications where +15 V supplies are common and headroom is important.

Higher bias levels are of limited value, partly because the resistor mentioned in the positive supply discussion must supply all the current devoted to the core, and partly because the core transistors become ineffective at logging and antilogging at currents over 1 mA.

Since pin 5 is intended as a current supply, not a voltage supply, bypassing at pin 5 is not necessary.

Pin 6 is used as a ground reference for the VCA. The non-inverting input of the internal op amp is connected here, as are various portions of the internal bias network. It may not be used as an additional input pin.

## Voltage Control

The primary voltage-control pin is pin 3. This point controls gain inversely with applied voltage: positive voltage causes loss, negative voltage causes gain. As described on Page 6, the current gain of the VCA is unity when pin 3 is at 0 V with respect to pins 2 and 4, and varies with voltage at approximately -6.1 mV/dB, at room temperature.

As implied by the equation for  $A_v$  (at the foot of Page 4), the gain is sensitive to temperature, in proportion to the amount of gain or loss commanded. The constant of proportionality is 0.33% of the decibel gain commanded, per degree Celsius, referenced to 27°C (300°K). This means that at 0 dB gain, there is no change in gain with temperature. However, at -122 mV, the gain will be +20 dB at room temperature, but will be 20.66 dB at a temperature 10°C lower. The formula is:

$$\text{Gain} = \frac{E_{C+} - E_{C-}}{(0.0061) (1 + 0.0033) \Delta T},$$

where  $E_C$  is in volts, and  $\Delta T$  is the difference between the actual temperature and room temperature (25°C).

For most audio applications, this change with temperature is of little consequence. However, if necessary, it may be compensated by a resistor which varies its value by .33%/°C. Such parts are available from RCD Components, Inc, 3301 Bedford St., Manchester, NH, USA [(603) 669-0054], and KOA/Speer Electronics, PO Box 547, Bradford, PA, 16701 USA [(814)362-5536].

When pin 3 is used for voltage control, pin 2 is connected to ground and pin 4 is used to apply a small

symmetry voltage (<math>\pm 2.5\text{ mV}</math>) to correct for  $V_{BE}$  mismatches within the VCA IC. For this purpose, the 2150 series devices were designed for optimum performance with an impedance of approximately  $50\Omega$  at pin 4. A trim pot is used to adjust the voltage between pin 4 and pin 2 as shown in Figure 3, Page 3. For supply voltages other than shown, scale  $R_{SYM}$  to provide the required adjustment range.

It is also possible to use pin 2 and pin 4 together as an opposite-sense voltage control port. A typical circuit using this approach is shown in Figure 14. Pin 3 may be grounded, and pin 2 driven against the symmetry-adjustment voltage. The change in voltage at pin 4 does have a small effect on the symmetry voltage, but this is of little practical consequence in most applications. Using the opposite sense of control can sometimes save an inverter in the control path.

It is also possible (and advantageous) to combine both control ports with differential drive (see Figure 15). While the driving circuitry is more complex, this configuration offers better performance at high attenuation levels (<math>< -90\text{ dB}</math>) where the single-control-port circuits begin to saturate Q1 (for  $E_{C-}$  drive) or Q3 (for  $E_{C+}$  drive). When either of these transistors saturates, the internal opamp will accommodate the change in current demand by responding with a small change in its input offset voltage. This leads to an accumulation of charge on the input capacitor, which in turn can cause thump when the high attenuation is suddenly removed (e.g., when a muted channel is opened). Differential control drive avoids the large dc levels oth-

erwise required to command high attenuation (+610 mV for -100 dB gain at pin 3 alone, vs.  $\pm 305\text{ mV}$  when using both pin 3 and pins 2 and 4).

### Control Port Drive Impedance

It has already been noted that the control port should be driven by a low source impedance for minimum distortion. This often suggests driving the control port directly with an opamp (see below under *Noise Considerations*). However, the closed-loop output impedance of an opamp typically rises at high frequencies due to falling loop gain. The output impedance is therefore inductive at high frequencies. Excessive inductance in the control port source impedance can cause the VCA to oscillate internally. In such cases, a  $51\Omega$  resistor in series with a 1.5 nF capacitor from the control port to ground will usually suffice to prevent the instability.

### Noise Considerations

It is second nature among good audio designers to consider the effects of noisy devices on the signal path. As is well known, this includes not only active devices such as op amps and transistors, but extends to the choice of impedance levels as well. High value resistors have inherent thermal noise associated with them, and the noise performance of an otherwise quiet circuit can be easily spoiled by the wrong choice of impedance levels.

Less well known, however, is the effect of noisy circuitry and high impedance levels in the control path of

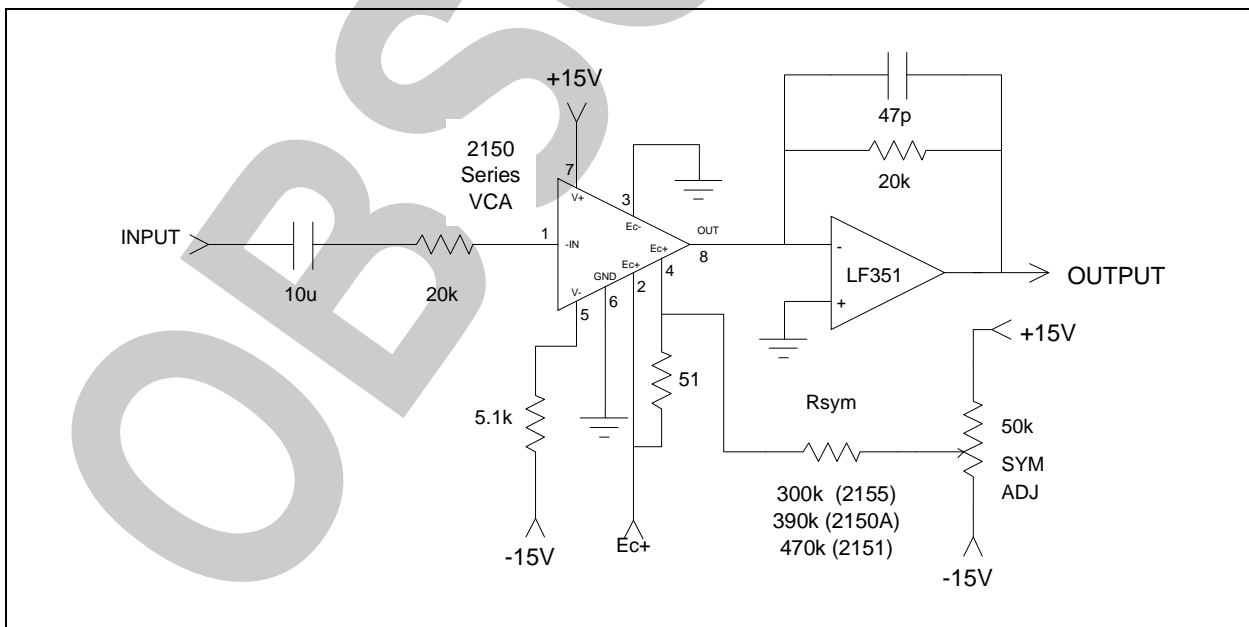

Figure 14. Positive Control Port Using Pins 2 and 4

voltage-control circuitry. The 2150 Series VCAs act like double-balanced multipliers: when no signal is present at the signal input, noise at the control input is rejected. So, when measuring noise (in the absence of signal — as most everyone does), even very noisy control circuitry often goes unnoticed. However, noise at the control port of these parts will cause noise modulation of the signal. This can become significant if care is not taken to drive the control ports with quiet signals.

The 2150 Series VCAs have a small amount of inherent noise modulation because of its class AB biasing scheme, where the shot noise in the core transistors reaches a minimum with no signal, and increases with the square root of the instantaneous signal current. However, in an optimum circuit, the noise floor rises only to -94 dBV with a 50  $\mu$ A signal at unity gain — 4 dB of noise modulation. By contrast, if a unity-gain connected, inverting 5534 opamp is used to directly drive the control port, the noise floor will rise to 92 dBV — 6 dB of noise modulation.

To avoid excessive noise, one must take care to use quiet electronics throughout the control-voltage circuitry. One useful technique is to process control voltages at a multiple of the eventual control constant (e.g., 61 mV/dB — ten times higher than the VCA requires), and then attenuate the control signal just before the final drive amplifier. With careful attention to impedance levels, relatively noisy op amps may be used for all but the final stage.

### Closing Thoughts

The design and application of Voltage-Controlled Amplifiers has traditionally been partly black art, involving as much magic as science. We hope that the foregoing discussion will help to de-mystify the subject.

THAT Corporation welcomes comments, questions and suggestions regarding these devices, their design and application. Please feel free to contact us with your thoughts.

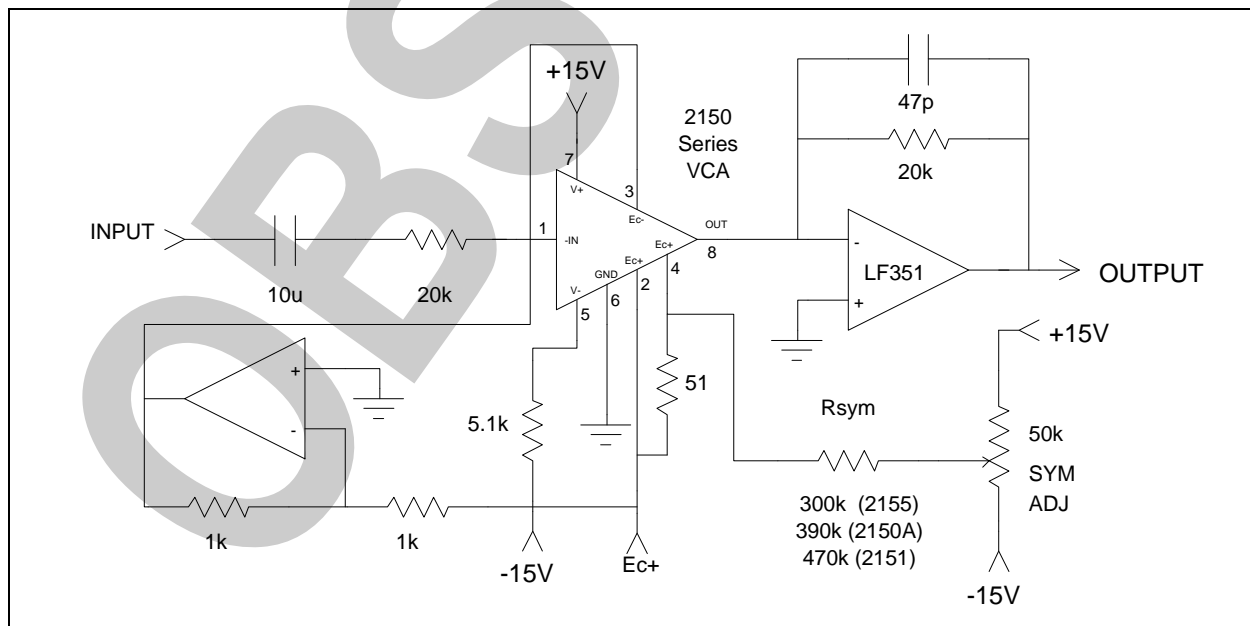

Figure 15. Using Both Control Ports (Differential Drive)
