

STPM10

Programmable single-phase energy metering IC with tamper detection

Features

- Measures active, reactive, and apparent energies
- Current, voltage RMS and instantaneous measurement
- Frequency measurement
- Ripple-free active energy pulsed output
- Live and neutral monitoring for tamper detection
- Fast and simple one-point digital calibration over the whole current range
- Integrated linear voltage regulators for digital and analog supply
- Selectable RC or crystal oscillator
- Supports 50 - 60 Hz - IEC62052-11, IEC62053-2x specifications
- Less than 0.1% error in the 1000:1 range
- Precision voltage reference: 1.23 V with 30 ppm/°C max

Description

The STPM10 is designed for effective measurement of active, reactive and apparent energy in a power line system using current transformer and shunt sensors. The device can be implemented for peripheral measurement in a microcontroller-based single-phase or poly-phase energy meter. The STPM10 consists of two main sections: analog and digital. The analog part is composed of preamplifier and first-order sigma-delta A/D converter blocks, a band-gap voltage reference and low-drop voltage regulator. The digital part is composed of system control, oscillator, hard-wired DSP and SPI interface. There is also an internal volatile memory, which is

controlled through the SPI by means of a dedicated command set. The configured bits are used for configuration and calibration purposes. From a pair of sigma-delta output signals produced by the analog section, the DSP unit computes the amount of active, reactive and apparent energy consumed, as well as the RMS and instantaneous voltage and current values. The results of the computation are available as pulse frequencies and states on the digital outputs of the device, or as data bits in a data stream, which can be read from the device by means of the SPI interface. The system bus interface is also used for temporary programming of bits of internal volatile memory. The STPM10 generates an output signal with a pulse frequency proportional to the energy, and this signal is used in the calibration phase of the energy metering application.

5 Terminology

5.1 Measurement error

The error associated with the energy measurement made by the STPM10 is defined as:
Percentage error = [STPM10 (reading) - true energy] / true energy

5.2 ADC offset error

This is the error due to the DC component associated with the analog inputs of the A/D converters. Due to the internal automatic DC offset cancellation, the STPM10 measurement is not affected by DC components in the voltage and current channel. The DC offset cancellation is implemented in the DSP.

5.3 Gain error

The gain error is gain due to the signal channel gain amplifiers. This is the difference between the measured ADC code and the ideal output code. The difference is expressed as percentage of the ideal code.

5.4 Power supply DC and AC rejection

This parameter quantifies the STPM10 measurement error as a percentage of the reading when the power supplies are varied. For the PSRRAC measurement, a reading at two nominal supply voltages (3.3 and 5 V) is taken. A second reading is obtained with the same input signal levels when an AC (200 mV_{RMS}/100 Hz) signal is introduced on the supplies. Any error introduced by this AC signal is expressed as a percentage of the reading. For the PSRRDC measurement, a reading at two nominal supply voltages (3.3 and 5 V) is taken. A second reading is obtained with the same input signal levels when the supplies are varied ± 10%. Any error introduced is again expressed as a percentage of the reading.

5.5 Conventions

The lowest analog and digital power supply voltage is called VSS, which represents system ground (GND). All voltage specifications for digital input/output pins are referred to GND.

Positive currents flow into a pin. Sinking current refers to the current flowing into the pin, and thus it is positive. Sourcing current means that the current is flowing out of the pin, so it is negative.

Timing specifications of signals treated by the digital control part are relative to CLKOUT. This signal is provided by the 4.194 MHz nominal-frequency crystal oscillator or from the internal RC oscillator. An external source of 4.194 MHz or 8.192 MHz can also be used.

Timing specifications of signals from the SPI interface are relative to the SCL, and there is no direct relationship between the clock (SCL) of the SPI interface and the clock of the DSP block. A positive logic convention is used in all equations.

7 Theory of operation

7.1 General operation description

The STPM10 is capable of performing measurements of active, reactive and apparent energy, RMS and instantaneous voltage and current values, and line frequency information.

Most of the functions are fully programmable using internal configuration bits accessible through the SPI interface. The STPM10 works as a peripheral in microcontroller-based metering systems. The ZCR and WDG pins are used to provide zero-crossing and watch-dog information, and the SPI pins are used to communicate with the microcontroller.

The STPM10 includes volatile internal registers that hold the useful information for the metering system. Two kinds of active energy are available: wide-band active energy (AW) which includes all harmonic content (also called type 0) and fundamental active energy (AF), limited to the 1st harmonic (also called type 1). This latter energy value is obtained by filtering type 0 active energy. Both the two active energies are stored in up-down counting accumulator registers with a 20-bit length. Reactive and apparent energies are also available with a 20-bit accumulation.

The STPM10 also provides the RMS values for voltage and current. Due to the modest dynamic variation of the voltage, the RMS value is stored with a resolution of 11 bits, while the RMS current value has a resolution of 16 bits. The instantaneous (momentary) sampled value of voltage and current are also available with a resolution of 11 and 16 bits, respectively. The line frequency value is stored with a resolution of 14 bits.

Due to the proprietary energy computation algorithm, the STPM10 calibration is quick and simple, allowing calibration at only one point over the entire current range.

The configuration and calibration parameters must be downloaded in the internal non-volatile memory of STPM10 at power-up.

7.2 Analog inputs

Input amplifiers

The STPM10 has one fully differential voltage input channel and two fully differential current input channels.

The voltage channel consists of a differential amplifier with a gain of 4. The maximum differential input voltage for the voltage channel is ± 0.3 V.

The two current channels are multiplexed (see [Chapter 7.9](#) for details) to provide a single input to a preamplifier with a gain of 4. The output of this preamplifier is connected to the input of a programmable gain amplifier (PGA) with possible gain selections of 2 and 8. The total gain of the current channels are then 8 and 32. The gain selections are made by writing to the gain register, and they can be different for the two current channels. If the tamper function is not used, the secondary current can be disabled.

The maximum differential input voltage is dependent on the selected gain, in accordance with [Table 6](#).

Table 6. Gain of voltage and current channels

Voltage channels		Current channels	
Gain	Max input voltage (V)	Gain	Max input voltage (V)
4	±0.30	8X	±0.15
		32X	±0.035

The gain register is included in the device configuration register with the address name PST. The table below shows the gain configuration according to the register values:

Table 7. Configuration of current sensors

Primary		Secondary		Configuration Bits	Configuration Bits
Gain	Sensor	Gain	Sensor	PST	TMP
8	CT	Disabled	Disabled	0	0
32	Shunt	Disabled	Disabled	1	0
8	CT	8	CT	0	1
8		32	Shunt	1	1

Note: If the device is used in configuration $PST = 1$, $TMP = 1$ (primary channel with CT, secondary channel with Shunt), the shunt K_s must always be equal to one fourth of the current transformer K_s .

Both the voltage and current channels implement an active offset correction architecture which provides the benefit of avoiding any offset compensation. The analog voltage and current signals are processed by the $\Sigma \Delta$ analog-to-digital converters, which feed the hard-wired DSP. The DSP implements an automatic digital offset cancellation that makes it possible to avoid any manual offset calibration on the analog inputs.

7.3 $\Sigma \Delta$ A/D converters

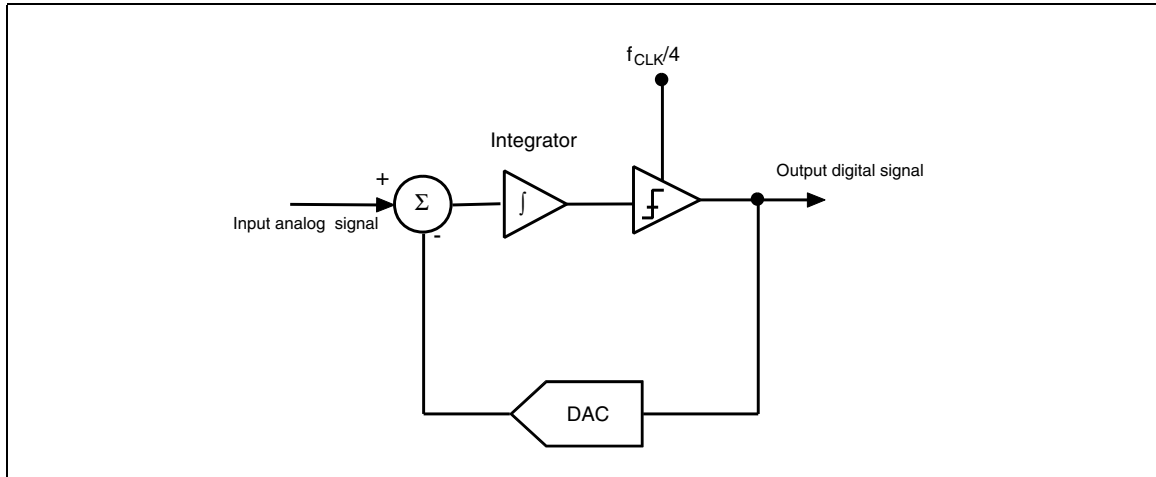

Analog-to-digital conversion in the STPM10 is carried out using two first-order $\Sigma \Delta$ converters. The device performs A/D conversions of analog signals on two independent channels in parallel. The current channel is multiplexed as a primary or secondary current channel in order to perform the tamper function, if enabled. The converted $\Sigma \Delta$ signals are supplied to the internal hard-wired DSP unit, which filters and integrates these signals in order to boost the resolution and to yield all the necessary signals for the computations.

A $\Sigma \Delta$ modulator converts the input signal into a continuous serial stream of 1's and 0's at a rate determined by the sampling clock. In the STPM10, the sampling clock is equal to $f_{CLK}/4$.

The 1-bit DAC in the feedback loop is driven by the serial data stream. The DAC output is subtracted from the input signal. If the loop gain is high enough, the average value of the DAC output (and therefore the bit stream) can approach that of the input signal level. When a large number of samples are averaged, a very precise value for the analog signal is obtained. This averaging is carried out in the DSP section, which implements decimation,

integration and DC offset cancellation of the supplied $\Sigma \Delta$ signals. The gain of the decimation filters is 1.004 for the voltage channel and 0.502 for the current channel. The resulting signal has a resolution of 11 bits per voltage channel and 16 bits per current channel.

Figure 14. First-order $\Sigma \Delta$ A/D converter

7.4 Zero-crossing detection

The STPM10 has a zero-crossing detector circuit on the voltage channel which can be used by application for synchronization of some utility equipment in the event of zero-crossing of the line voltage. This circuit produces the internal signal ZCR which has a rising edge every time the line voltage crosses zero, and a negative edge every time the voltage reaches its positive or negative peak. The ZCR signal is then at twice the line voltage frequency. The ZCR signal is available on the ZCR pin.

Figure 15. ZCR signal

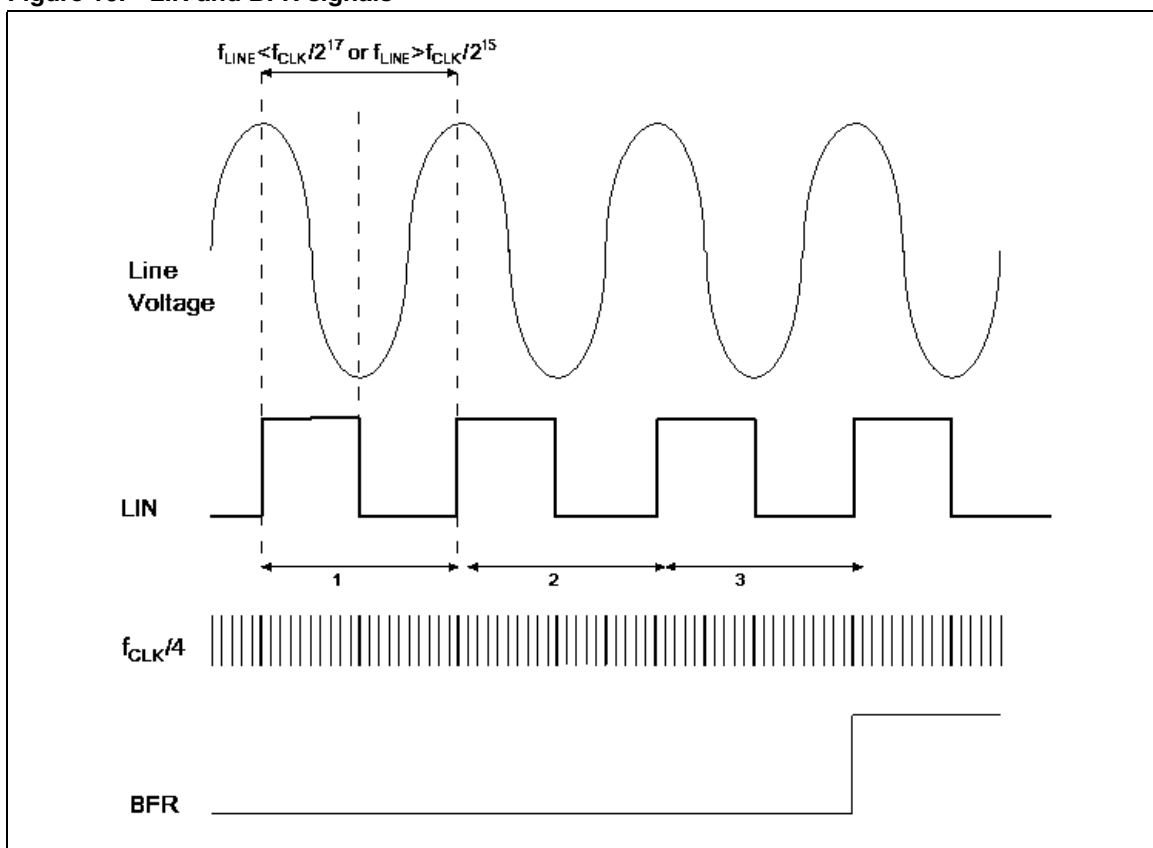

7.5 Period and line voltage measurement

The period module measures the period of the base frequency of the voltage channel and checks if the voltage signal frequency is within the $f_{\text{CLK}}/2^{17}$ to $f_{\text{CLK}}/2^{15}$ band. To do this, the LIN signal is produced, which is low when the line voltage is rising, and high when the line voltage is falling. This means that the LIN signal is the sign of dv/dt . With further elaboration, the ZCR signal is also produced. On the trailing edge of LIN (line frequency) the period counter starts counting up pulses of the $f_{\text{CLK}}/4$ reference signal. The LIN signal is available on the status bit register (see [Table 10](#)).

If the counted number of pulses between two trailing edges of LIN is higher than 2^{15} , or if the counting is never stopped (no LIN trailing edge) this means that the base frequency is lower than $f_{\text{CLK}}/2^{17}$ Hz and a BFR (base frequency range) error flag is set.

Figure 16. LIN and BFR signals

If the number of pulses counted between two trailing edges of LIN is lower than 2^{13} , the base frequency exceeds the limit (this means it is higher than $f_{\text{CLK}}/2^{15}$). In this case, the error must be repeated three consecutive times in order to set the BFR error flag.

For example, with a 4.194304 MHz oscillator frequency and MDIV bit clear (or 8.192 MHz with MDIV set), $f_{\text{CLK}}/4$ is 1.048576 MHz. If the line frequency is 30 Hz, the counted $f_{\text{CLK}}/4$ pulses between two LIN trailing edges are 34952, more than 2^{15} (32768 pulses).

The BFR low frequency limit is then:

$$f_{\text{CLK}}/2^{17} = 4194304/131072 = 32 \text{ Hz}$$

With the same clock frequency, if the line frequency is 130 Hz, the $f_{CLK}/4$ pulses between two LIN trailing edges are 8066, less than 2^{13} (8192). The BFR high frequency limit is then:

$$f_{CLK}/2^{15} = 4194304/32768 = 128 \text{ Hz.}$$

The BFR flag is also set if the register value of the RMS voltage drops below 64. BFR is cleared when the register value goes above 128. The BFR, then, also gives information about the presence of the line voltage within the meter.

When the BFR error is set, the computation of power is zero unless the FRS bit is set.

In fact, the effect of the BFR bit can be overridden by setting FRS configuration bit.

It means that if FRS is set and BFR is also set, all the energy computation is carried on as BFR was cleared. In this case then $p=u*i$, where u could be zero or not (if BFR was set because voltage RMS register value is below 64).

When the line frequency re-enters the nominal band, the BFR flag is automatically reset. This BFR error flag is also assembled as part of the 8-bit status register (see [Table 10](#)).

7.6 Power supply

The main STPM10 supply pin is the VCC pin. From the VCC pin two linear regulators provide the necessary voltage for the analog part VDDA (3 V) and for the digital part VDDD (1.8 V).

The VSS pin represents the reference point for all the internal signals. A 100 nF low ESR capacitor should be connected between VCC and VSS, VDDA and VSS, VDDD and VSS. All these capacitors must be located very close to the device.

The STPM10 contains a power on reset (POR) detection circuit. If the VCC supply is less than 2.5 V, then the STPM10 goes into an inactive state, all the functions are blocked and a reset condition is asserted. This is useful to ensure correct device operation at power-up and during power-down. The power supply monitor has built-in hysteresis and filtering, which give a high degree of immunity from false triggering due to noisy supplies.

A band-gap voltage reference (VBG) of $1.23 \text{ V} \pm 1\%$ is used as the reference voltage level source for the two linear regulators and for the A/D converters. Also, this module produces several bias currents and voltages for all other analog modules. The band-gap voltage can be compensated regardless of the temperature variations with the BGTC bits.

Figure 17. Band-gap temperature variation

7.7 Load monitoring

The STPM10 includes a no-load condition detection circuit with adjustable threshold. This circuit monitors the voltage and the current channels and, when the measured voltage is below the set threshold, the internal signal BIL becomes high. Information about this signal is also available in the status bit BIL.

The no-load condition occurs when the product of the VRMS and IRMS register values is below a given value. This value can be set with the LTCH configuration bits. Four different no-load threshold values can be chosen according to the two configuration bits LTCH (see [Table 8](#)).

When a no-load condition occurs (BIL=1) the integration of power is suspended and the tamper module is disabled. The BIL signal can be accessed only through the SPI interface.

Table 8. No-load detection thresholds

LTCH	K_{LTCH}
0	800
1	1600
2	3200
3	6400

7.8 Error detection

In addition to the no-load condition and the line frequency band, the integration of power can also be suspended due to an error detected on the source signals.

There are two kinds of error-detection circuits involved. The first checks all the $\Sigma \Delta$ signals from the analog part if any is stacked at 1 or 0 within the $1/128$ of f_{CLK} period of observation.

In case of a detected error, the corresponding $\Sigma \Delta$ signal is replaced with an idle $\Sigma \Delta$ signal, which represents a constant value of 0. All error and other resolved flags are treated as bits of a device status and can be read out by means of the SPI interface.

Another error condition occurs if LED pin output signals are different from the internal signals that drive them. This can occur if some of these pins are forced to GND or to some other imposed voltage value. In this case, the internal status bit PIN is activated, providing the information that some hardware problem has been detected.

7.9 Tamper detection module

The STPM10 is able to measure the current in both live and neutral wire with a time domain multiplexing approach on a unique sigma delta modulator. This mechanism is adopted to implement anti-tamper function. If this function is selected (see [Table 7](#)), the live and neutral wire currents are monitored; when the difference between the two measurements exceeds a rated threshold the STPM10 enters the "tamper state", while in "normal state" the two measurements are below the threshold.

In particular, both channels are not observed all the time, rather a time multiplex mechanism is used. During the observation time of each channel, its active energy is calculated. A tamper condition occurs when the absolute value of the difference between the two active

energy values is greater than a certain percentage of the averaged energy during the activated tamper module (see [Equation 1](#)).

This percentage value can be selected between two different values (12.5 % and 6.25 %) according to the value of the configuration bit CRIT.

The tamper condition is detected when the following formula is satisfied:

Equation 1

$$\text{EnergyCH1} - \text{EnergyCH2} > K_{\text{CRIT}} (\text{EnergyCH1} + \text{EnergyCH2})/2;$$

where K_{CRIT} can be 12.5 % or 6.25 %.

The detection threshold is much higher than the accuracy difference of the current channels, which should be less than 0.2 %, but, some headroom should be left for possible transition effect, due to accidental synchronism of actual load current change with the rhythm of taking the energy samples.

The tamper circuit works if the energies associated with the two current channels are both positive or negative, if the two energies have different sign, the tamper is on all the time however, the channel with the associated higher power is selected for the final computation of energy.

When internal signals are not good enough to perform the calculations, i.e. line period is out of range or $\Delta\Sigma$ signals from analog section are stacked at high or low logic level, or no load condition is activated, the tamper module is disabled and its state is preset to normal.

7.9.1 Detailed operational description

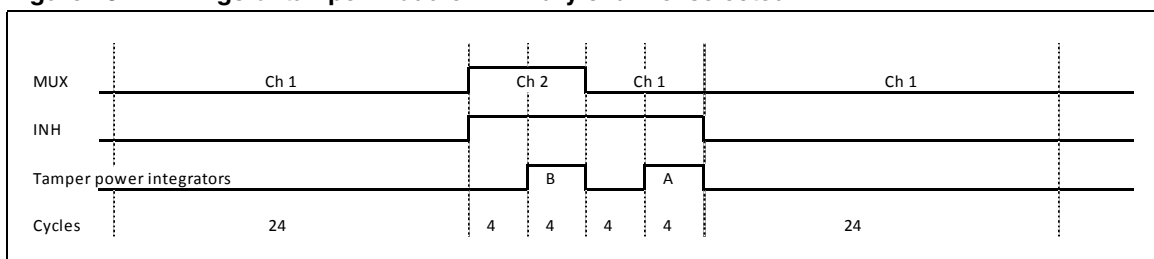

The meter is initially set to normal state, i.e. tamper not detected. In this condition the primary channel is selected for final integration of energy. In such state the values of both load currents should not differ more than the accuracy difference of the channels does. Sixty-four periods of line voltage is used as a tamper checking period.

After 24 periods of line voltage two internal signals MUX and INH are changed in order to enable secondary current channel and to freeze the last power and RMS values of primary current channel. The following 16 periods of line frequency are used for tamper detection integration. During this gap, the final energy calculation does not use the signal from selected channel but the frozen values.

Four line periods after the INH switch, the integration of power from secondary current channel is started and lasts four periods. Additional four line periods later MUX signal is switched back to primary current channel and the integration for tamper detection is started.

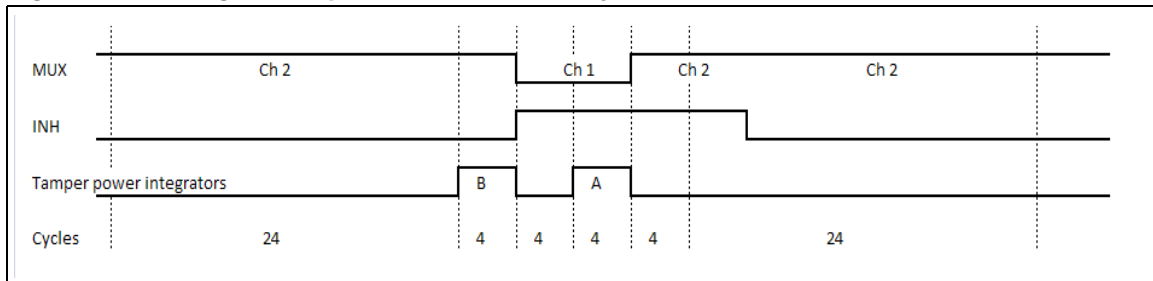

The timings of MUX and INH signals are shown in [Figure 18](#) below.

Figure 18. Timings of tamper module - Primary channel selected

When the secondary channel is selected to be integrated by the final energy integrator, the MUX and INH signals change according to [Figure 19](#) below.

Figure 19. Timings of tamper module - Secondary channel selected

This means that energy of four periods from secondary channel followed by energy of four periods from primary channel is sampled within the tamper module. From these two samples, called B and A respectively, the criteria of tamper is calculated and the channel with higher current is selected, resulting in a new tamper state. If four consecutive new results of criteria happen, i.e. after elapsed 5.12 s at 50 Hz, the meter will enter into tamper state. Thus, the channel with the higher current will be selected for the energy calculation. If samples of power A and B would have different signs, the Tamper would be on all the time but, the channel with bigger power would be still selected for the final integration of energy.

If a tamper status has been detected, the multiplex ratio will be 56:8 if the primary channel energy is greater than the secondary one, otherwise it will be 8:56.

The detected tamper condition is stored in the BIT status bit. If BIT = 0 tamper is not detected, if BIT = 1 a tamper condition has been detected. In standalone mode the BIT flag is also available in the SDATD pin.

7.10 Phase compensation

The STPM10 does not introduce any phase shift between the voltage and current channel. However, the voltage and current signals come from transducers, which could have inherent phase errors. For example, a phase error of 0.1° to 0.3° is not uncommon for a current transformer (CT). These phase errors can vary from part to part, and they must be corrected in order to perform accurate power calculations. The errors associated with phase mismatch are particularly noticeable at low power factors. The STPM10 provides a means of digitally calibrating these small phase errors by introducing delays on the voltage or current signal. The amount of phase compensation can be set using the 4 bits of the phase calibration register (CPH).

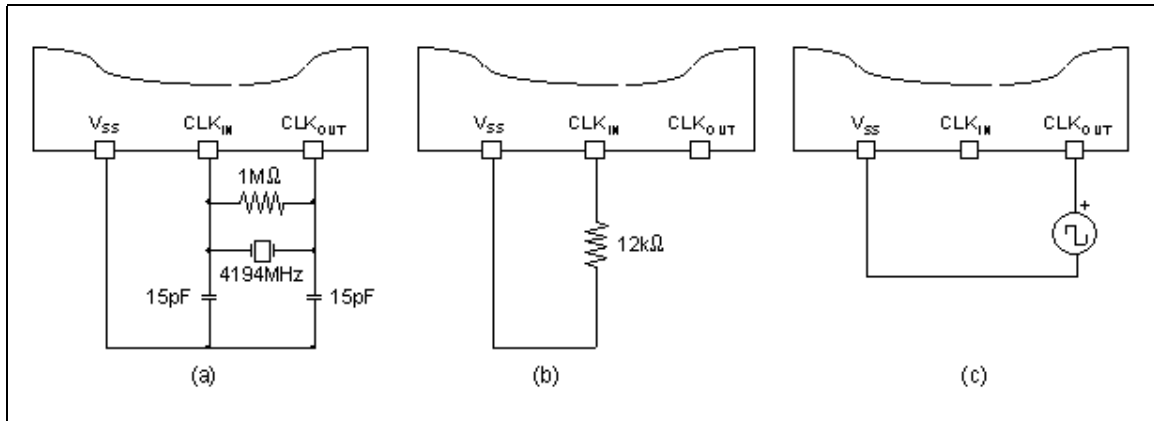

The default value of this register is at a value of 0, which gives 0° phase compensation. When the 4 bits give a CPH of 15 (1111) the compensation introduced is $+0.576^\circ$. This compensates the phase shift usually introduced by the current sensor, while the voltage sensor, normally a resistor divider, does not introduce any delay. The resolution step of the phase compensation is 0.038° .

7.11 Clock generator

All the internal timing of the STPM10 is based on the CLKOUT signal. This signal can be generated in three different ways:

1. RC: this oscillator mode can be selected using the RC configuration bit. If RC = 1, the STPM10 runs using the RC oscillator. A resistor connected between CLKIN and ground sets the RC current. For 4 MHz operation, the recommended settling resistor is 12 k Ω . The oscillator frequency can be compensated using the CRC configuration bit.
2. Quartz: If RC = 0, the oscillator works with an external crystal. The recommended circuit is depicted in [Figure 20](#) (b).
3. External clock: by keeping RC=0, it is also possible to feed the CLKOUT pin with an external oscillator signal.

Figure 20. Different oscillator circuits with (a) quartz, (b) internal oscillator, (c) external source

The clock generator is powered from an analog supply and is responsible for two tasks. The first is to retard the turn-on of some function blocks after POR in order to help smooth the start of the external power supply circuitry by keeping off all major loads. The second task of the clock generator is to provide all necessary clocks for the analog and digital parts. During this task, the MDIV configuration bit is used to inform the device about the nominal frequency value of CLKOUT. Two nominal frequency ranges are expected to be from 4.000 MHz to 4.194 MHz (MDIV = 0) or from 8.000 MHz to 8.192 MHz (MDIV = 1).

7.11.1 RC startup procedure

To use the device with RC oscillator the configuration bit RC (see [Table 11](#)) must be set. Since the default configuration is for a crystal oscillator, when a RC oscillator is used instead and the device is supplied for the very first time it is not internally clocked and consequently the DSP is inactive. In this condition it is not possible to set RC or any other configuration bit.

The following SPI procedure can be run in order to set the RC bit and provide the clock to the device:

- Set the mode signal BANK;
- Perform a software reset;
- Read the registers: BANK mode signal should be checked and the records should show something (not 00000F0);
- Clear the mode signal BANK;
- DO NOT perform a reading, and write configuration bit RC;

In this way the RC oscillator is started. If the registers are read again, it can be seen that RC bit is set and BANK is cleared. Once the RC startup procedure is complete, the device is clocked and active. For details on mode signals refer to [Chapter 7.18](#), for SPI operations refer to [Chapter 7.19](#).

7.12 Resetting the STPM10

The STPM10 has no reset pin. The device is automatically reset by the POR circuit when the V_{CC} crosses the 2.5 V value, but it can also be reset through the SPI interface by providing a dedicated command (see [Section 7.19](#) for remote reset command details).

In case of reset caused by the POR circuit, all clocks and both DC buffers in the analog part are kept off for about 30 ms, as well as all blocks of the digital part, except for the SPI interface, which is held in a reset state for about 125 ms after a reset condition.

When a reset is performed through SPI, no delayed turn-on is generated.

Resetting the STPM10 causes all the functional modules of the STPM10 to be cleared, including the volatile memory.

The reset through SPI (remote reset request) normally takes place during production testing.

7.13 Using the STPM10 in microcontroller-based meters

The STPM10 can be used in microcontroller-based energy meters.

The SPI pins (SCS, SCL, SDA, SYN) are used for communication purposes, allowing the microcontroller to write and read the internal STPM10 registers.

The zero-crossing signal is available at the ZCR pin (see [Section 7.4](#) for details about the ZCR signal).

The WDG pin provides the watchdog signal (DOG). The DOG signal generates a 16 ms long positive pulse every 1.6 seconds. Generation of these pulses can be suspended if data are read in intervals shorter than 1.6 s. The DOG signal is actually a watchdog reset signal which can be used to control operation of an on-board microcontroller. It is set to high whenever the VDDA voltage is below 2.5 V, but after VDDA goes above 2.5 V this signal starts running.

It is expected that an application microcontroller should access the data in the metering device on a regular basis at least 1/s (recommended is 32/s). Every latching of results in the metering device requested from the microcontroller also resets the watchdog. If latching requests are not 1.6 seconds from one another, an active high pulse on WDG is produced, because the device assumes that the microcontroller is not operating properly. An application can use this signal either to control the reset pin of its microcontroller, or it can be tied to an interrupt pin. The latter option is recommended for a battery-backup application which can enter a sleep mode due to power-down conditions, and should not be reset by a metering device as it would exit from sleep mode.

7.14 Energy to frequency conversion

The STPM10 provides energy to frequency conversion both for calibration and energy readout purposes. In fact, one convenient way to verify the meter calibration is to provide a pulse train signal with 50% duty cycle whose frequency signal is proportional to the active energy under steady load conditions. In this case, the user chooses a certain number of pulses on the LED pin that correspond to 1 kWh. This value is called P.

Let us consider the case in which the LED pin is configured to be driven from internal signal AW (active energy) whose frequency is proportional to the active energy. The signal AW is

taken from the 11th bit of the active energy register, and consequently a relationship between the LSB value of the active energy register and the number of pulses provided per each kWh (P) can be defined as:

Equation 2

$$k_{AW} = \frac{1000}{2^{11} \cdot P} [\text{Wh}]$$

Due to the innovative and proprietary power calculation algorithm, the frequency signal is not affected by any ripple at twice the line frequency. This feature strongly reduces the calibration time of the meter.

In a practical example where the desired P is 64000 pulses/kWh (=17.7 Hz*kW), we have:

Equation 3

$$k_{AW} = 7.63 \cdot 10^{-6} \text{ Wh}$$

This means that the reading of 0x00001 in the active energy register represents 7.63 μWh, while 0xFFFFF represents 8 Wh.

The LED pin can be driven from AW (active energy wide band), AF (active energy limited at fundamental), RW (reactive energy) or SW (apparent energy) according to the value of the KMOT bit.

In this case, since the LED pin is driven by signals different from that of AW, some other relationship between the LSB of the register and the number of pulses per kWh provided by the meter (P) must be defined:

Equation 4

$$k_{AF} = 4 \cdot k_{AW} [\text{Wh}]$$

$$k_{RW} = 2 \cdot k_{AW} [\text{VARh}]$$

$$k_{SW} = k_{AW} [\text{VAh}]$$

Table 9. LED pin configuration

KMOT (2 bits)	Signal available on LED pin	# of pulses
0	AW Type0*	P [kWh]
1	AF Type1*	P [kWh]
2	RW	P [kVARh]
3	SW	P [kVAh]

7.15 Status bits

The STPM10 includes 8 status bits which provide information about the current status of the meter. The status bits are the following:

Table 10. Status bit description

Bit #	Name	Description	Condition
0	BIL	No-load condition	BIL = 0: No-load condition not detected
			BIL = 1: No-load condition detected
1	BCF	$\Sigma \Delta$ signals status	BCF = 0: $\Sigma \Delta$ signals active
			BCF = 1: One or both $\Sigma \Delta$ signals are stacked
2	BFR	Line frequency range	BFR = 0: Line frequency within the 45 Hz - 65 Hz range
			BFR = 1: Line frequency out of range
3	BIT	Tamper condition	BIT = 0: Tamper not detected
			BIT = 1: Tamper detected
4	MUX	Current channel selection	MUX = 0: Primary current channels selected by the tamper module
			MUX = 1: Secondary current channels selected by the tamper module
5	LIN	Trend of the line voltage	LIN = 0: Line voltage going from the minimum to the maximum value. ($dv/dt > 0$)
			LIN = 1: Line voltage going from the maximum to the minimum value. ($dv/dt < 0$)
6	PIN	Output pin check	PIN = 0: Output pins are consistent with the data
			PIN = 1: Output pins are different with the data, this means an output pin is forced to 1 or 0
7	HLT	Data validity	HLT = 0: Data records reading are valid.
			HLT = 1: Data records are not valid. A reset occurred and a restart is in progress

All these signal can be read through the SPI interface. See [Section 7.15: Status bits](#) for details on the status bit location in the STPM10 data records.

7.16 Programming the STPM10

7.16.1 Data records

The STPM10 has 8 internal data record registers. Every data record consists of a 4-bit parity code and 28-bit data value where the parity code is computed from the data value, which makes a total of 32 bits, or 4 bytes.

Figure 21 shows the data record structure with the name of the contained information. Each bit of parity nibble is defined as odd parity of all seven corresponding bits of data nibbles.

The first 6 registers are read-only, except for the 8-bit mode signals in the DFP register (the mode signals are described later in this paragraph). The last two registers are CFL and CFH.

Figure 21. STPM10 data records map

7.17 Configuration bits

All the configuration bits that control the operation of the device (CFL and CFH data records) can be written in a temporary way. The configuration bit values are written in the so-called volatile memory, which are simple latches that hold the configuration data until the power is on or until a reset condition occurs (both POR and remote reset).

As indicated in the data records table, the configuration bits are 56.

Each configuration bit can be written by sending a byte command to STPM10 through its SPI interface. The procedure to write the configuration bits is described in [Section 7.19: SPI interface](#).

Table 11. Configuration bit map

Address		Name	n. of bits	Description ⁽¹⁾
6-bit binary	DEC			
000000	0	-	1	Reserved
000001	1	MDIV	1	Measurement frequency range selection: - MDIV=0: 4.000 MHz to 4.194 MHz - MDIV=1: 8.000 MHz to 8.192 MHz
000010	2	RC	1	Type of internal oscillator selection: - RC=0: crystal oscillator, - RC=1: RC oscillator
000011	3	-	1	Reserved
000100	4	-	1	Reserved
000101	5	PST	1	Current channel sensor type and gain: If TMP=0 PST=0: primary is CT x8, secondary is not used, no tamper PST=1: primary is shunt x32, secondary is not used, no tamper
				If TMP=1 PST=0: primary is CT x8, secondary is CT x8, tamper PST=1: primary is CT x8, secondary is shunt x32, tamper
000110	6	-	1	Reserved
000111	7	TMP	1	Tamper enable
001000	8	FRS	1	Power calculation when BFR=1 - FRS=0: energy accumulation is frozen, power is set to zero; - FRS=1: normal energy accumulation and power computation ($p=u*i$);
001001	9	MSBF	1	Bit sequence output during record data reading selection: - MSBF=0: MSB first - MSBF=1: LSB first
001010	10	FUND	1	This bit swaps the information stored in the type0 (first 20 bits of DAP register) and type1 (first 20 bits of DFP register) active energy. - FUND = 0: type 0 contains wide-band active energy, type1 contains fundamental active energy - FUND = 1: type 0 contains fundamental active energy, type1 contains wide-band active energy
001100	12	LTCH	2	No-load condition threshold as product between V_{RMS} and I_{RMS} : LTCH=0 800 LTCH=1 1600 LTCH=2 3200 LTCH=3 6400

110111	55	-	1	Reserved (always set to 1 after production testing of die)

1. IMPORTANT: This bit represents the MSB of the decimal value indicated in the description column.

As indicated above, the STPM10 includes 56 CFG bits. The CFG bits are not retained when the STPM10 supply is not available and they are cleared when a POR occurs, but they are not cleared when a remote reset command (RRR) is sent through SPI.

Normally, some of these bits must be loaded during power-up of the application. From the microcontroller, it could also reload the configuration and calibration values after power-on restart.

7.18 Mode signals

The STPM10 includes 8 mode signals located in the DFP data record. 3 of these are used only for internal testing purposes while 5 are useful to change some of the operations of the STPM10. The mode signals are not retained when the STPM10 supply is not available and they are cleared when a POR occurs, but they are not cleared when a remote reset command (RRR) is sent through SPI.

The mode signals bit can be written using the normal writing procedure of the SPI interface (see [Section 7.19](#)).

Table 12. Mode signal description

Bit #	Signal name	Bit value	Status	Binary command	Hex command
0	BANK	0	Used for RC startup procedure	0111000x	70 or 71
		1		1111000x	F0 or F1
1	Reserved				
2	Reserved				
3	Reserved				

Table 12. Mode signal description (continued)

4	CSEL	0	Current channel 1 selected when tamper is disabled	0111 100x	78 or 79
		1	Current channel 2 selected when tamper is disabled	1111 100x	F8 or F9
5	Reserved				
6	Reserved				
7	Precharge	1	Swap the 32-bit data record readings. From 1,2,3,4,5,6,7,8, to 5,6,7,8,1,2,3,4 and vice-versa	1111111x	FF

- **CSEL:** In normal operation, if the anti-tamper module is not activated (see PST configuration bits) the STPM10 selects channel 1 as the source of current information. For debug or calibration purposes it is possible to select channel 2 as the source of the current channel signal when the tamper module is disabled. This is done by setting the CSEL mode bit.
- **Precharge:** This command swaps the sequence of data records read, allowing the reading of the last four data records first, and the first four second. The reading sequence is 5, 6, 7, 8, 1, 2, 3, 4. Unlike the other mode signals, the precharge command is not retained inside the STPM10, but should be sent each time before the reading of the data records.
- **BANK:** it is used to activate RC oscillator (see [Chapter 7.11.1](#)).

7.19 SPI interface

The SPI interface supports a simple serial protocol, which is implemented to enable communication between some master system (microcontroller or PC) and the device.

Three tasks can be performed with this interface:

- remote resetting of the device
- reading data records
- writing the mode bits and the configuration bits

Four pins of the device are dedicated to this purpose: SCS, SYN, SCL and SDA.

SCS, SYN and SCL are all input pins, while SDA can be input or output according to whether the SPI is in write or read mode. A high-level signal for these pins means a voltage level higher than $0.75 \times VCC$, while a low-level signal means a voltage value lower than $0.25 \times VCC$.

The internal registers are not directly accessible. Instead, 32 bits of transmission latches are used to pre-load the data before being read or written to the internal registers.

The condition in which SCS, SYN and SCL inputs are set to high level determines the idle state of the SPI interface, and no data transfer occurs.

- **SCS:** enables SPI operation when low.
- **SYN:** operates different functions according to the status of the SCS pin. When SCS is low, the SYN pin status selects if the SPI is in read (SYN = 1) or write mode (SYN = 0). When the SCS is high and SYN is also high, the results of the input or output data are transferred to the transmission latches.
- **SCL:** basically the clock pin of the SPI interface. This pin function is also controlled by the SCS status. If SCS is low, SCL is the input of the serial bit synchronization

clock signal. When SCS is high, SCL is also high, determining the idle state of the SPI.

- SDA: the data pin. If SCS is low, the operation of SDA is dependent on the status of the SYN pin. If SYN is high, SDA is the output of the serial bit data (read mode). If SYN is low, SDA is the input of the serial bit data signal (write mode). If SCS is high, SDA is the input of the idle signal.

Any pin above has an internal weak pull-up mechanism of nominal 15 μ A. This means that when a pin is not forced by external signals, the state of the pin is logic high. A high state of any input pin described above is considered an idle (not active) state. For the SPI to operate correctly, the STPM10 must be correctly supplied as described in [Section 7.6: Power supply](#). An idle state of the SPI module is recognized when the signals of pins SYN, SCS, SCL and SDA are in a logic high state. Any SPI operation should start from this idle state.

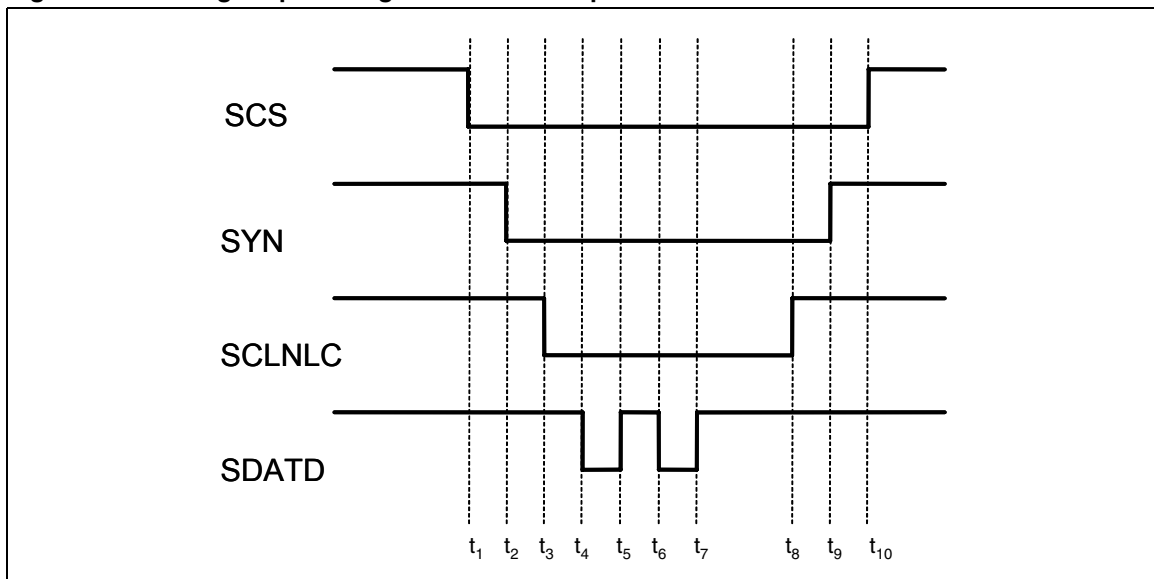

When SCS is active (low), signal SDATD should change its state at trailing edge of signal SCLNLC and the signal SDATD should be stable at next leading edge of signal SCLNLC. The first valid bit of SDATD is always started with activation of signal SCLNLC.

7.20 Remote reset

The timing diagram of this operation is shown in [Figure 22](#). The time step can be as short as 30 ns.

The internal reset signal is called RRR. Unlike the POR, the RRR signal does not cause the 30 ms delayed restart of the analog module, and the 120 ms delay in the restart of the digital module. This signal does not clear the mode signals.

Figure 22. Timing for providing remote reset request ⁽¹⁾

1. All time intervals must be longer than 30 ns. $t_7 \rightarrow t_8$ is the reset time; this interval must be longer than 30 ns also.

7.21 Reading data records

A microcontroller is able to read all measurement results and all system signals (configuration, calibration, status, mode). Again, the time step can be as short as 30 ns. There are two phases of reading, called latching and shifting.

Latching is used to sample results into transmission latches. The transmission latches are the flip-flops that hold the data in the SPI interface. This is done with the active pulse on SYN when SCS is idle. The length of the pulse on SYN must be longer than 2 periods of the measurement clock, i.e. more than 500 ns at 4 MHz.

The shifting starts when SCS become active. In the beginning of this phase, another much shorter pulse (30 ns) on SYN should be applied in order to ensure that an internal transmission serial clock counter is reset to zero. An alternative way is to extend the pulse on SYN into the second phase of reading. After this reset is done, a 32 serial clocks-per-data record should be applied. Up to 8 data records can be read this way. This procedure can be aborted at any time through deactivation of SCS (see [Figure 24](#)).

The first read-out byte of the data record is the least significant byte (LSB) of the data value and, of course, the fourth byte is the most significant byte (MSB) of the data value. Each byte can be further divided into a pair of 4-bit nibbles, referred to as the most and least significant nibble (MSN, LSN). This division makes sense with the MSB of the data value because its MSN holds the parity code rather than useful data.

The sequence of the data record during the read operation is fixed. Normally, an application reads the 1st through the 6th data record; the 7th and 8th data record would be read only when it needs to fetch the configuration data. However, an application may apply a precharge command (see [Table 12](#)) prior to the reading phase. This command forces the device to respond with the sequence 5th - 8th, 1st - 4th. Such a change of sequence can be used to skip the first four data records.

The timing diagram of the reading operation is shown in [Figure 24](#). One can see the latching and beginning of the shifting phase of the first byte (0x5F) of the first data record, and the end of reading. Also, both alternatives for resetting the internal transmission serial clock counter are shown in signal SYN.

Figure 23. Data record reconstruction

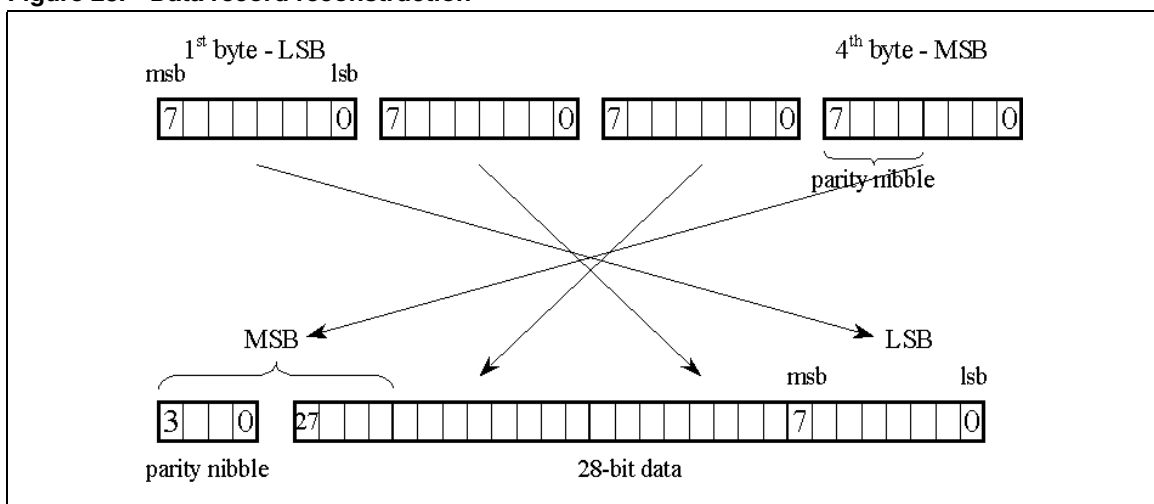

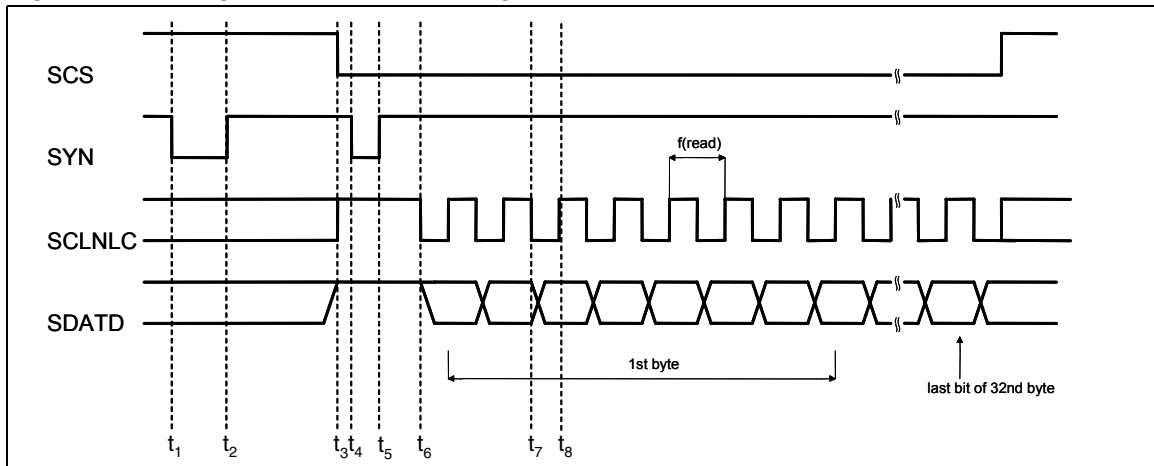

Figure 24. Timing for data record reading

- $t_1 \rightarrow t_2$: Latching phase. Interval value $> 2/f_{CLK}$
- $t_2 \rightarrow t_3$: Data latched, SPI idle. Interval value > 30 ns
- $t_3 \rightarrow t_4$: Enable SPI for read operation. Interval value > 30 ns
- $t_4 \rightarrow t_5$: Serial clock counter is reset. Interval value > 30 ns
- $t_5 \rightarrow t_6$: SPI reset and enabled for read operation. Interval value > 30 ns
- t_7 : Internal data transferred to SDA
- t_8 : SDA data is stable and can be read

The system that reads the data record from the STPM10 should check the integrity of each data record. If the check fails, the reading should be repeated, but this time only the shifting should be applied. Otherwise, new data would be latched into transmission latches and the one incorrectly read would be lost.

Normally, each byte is read out as the most significant bit (MSB) first. But this can be changed by setting the MSBF configuration bit in the STPM10 CFL data record. If this is done, each byte is read out as the least significant bit (LSB) first.

7.22 Writing procedure

Each writable bit (configuration and mode bits) has its own 6-bit absolute address. For the configuration bits, the 6-bit address value corresponds to its decimal value, while for the mode bits the addresses are the ones indicated in [Section 7.18: Mode signals](#).

In order to change the state of a latch, one must send a byte of data to the STPM10, which is the normal way to send data via SPI. This byte consists of 1-bit data to be latched (MSB), followed by the 6-bit address of the destination latch, followed by 1-bit don't care data (LSB), which makes a total of 8 bits of command byte.

For example, if we want to set configuration bit 47 (part of the secondary current channel calibrator) to 0, we must convert the decimal 47 to its 6-bit binary value: 101111. The byte command is then composed as follows:

1 bit DATA value+6-bits address+1 bit (0 or 1) as depicted in [Figure 25](#). In this case the binary command is 01011111 (0x5F), which is the one depicted, or 01011110 (0x5E):

Figure 25. Timing for writing configuration and mode bits

- $t_1 \rightarrow t_2$ (> 30 ns): SPI out of idle state
- $t_2 \rightarrow t_3$ (> 30 ns): SPI enabled for write operation
- t_3 : data value is placed in SDA
- t_4 : SDA value is stable and shifted into the device
- $t_3 \rightarrow t_5$ (> 10 μ s): writing clock period
- $t_3 \rightarrow t_5$: 1 bit data value
- $t_5 \rightarrow t_6$: 6 bit address of the destination latch
- $t_6 \rightarrow t_7$: 1 bit EXE command
- t_8 : end of SPI writing
- t_9 : SPI enters idle state

The same procedure should be applied for the mode signals, but in this case the 6-bit address must be taken from [Table 12](#).

The LSB of the command is also called the EXE bit because instead of the data bit value, the corresponding serial clock pulse is used to generate the necessary latching signal. This way the writing mechanism does not need the measurement clock in order to operate, which makes the operation of SPI module of STPM10 completely independent from the rest of device logic except for the signal POR.

Commands for changing system signals should be sent during active signals SCS and SYN, as shown in [Figure 25](#). The SYN must be put low in order to disable the SDA output driver of the STPM10 and make the SDA an input pin. A string of commands can be sent within one period of active SCS and SYN signals, or a command can be followed by reading the data record. However, in this case, the SYN should be deactivated in order to enable the SDA output driver, and a SYN pulse should be applied before activation of the SCS in order to latch the data.

7.22.1 Interfacing the standard 3-wire SPI with the STPM10 SPI

Due to the fact that a 2-wire SPI is implemented in the STPM10, it is clear that sending any command from a standard 3-wire SPI would require a 3-wire to 2-wire interface, which should produce a proper signal on SDA from host signals SDI, SDO and SYN. The need for a single-gate 3-state buffer could be avoided through an emulation of SPI just to send some commands. On a microcontroller this would be done by performing the following steps:

1. Disable the SPI module
2. Set the SDI pin, which is connected to SDA as an output
3. Activate SYN first, and then SCS
4. Apply a new bit value to SDI, and activate SCL
5. Deactivate SCL
6. Repeat the previous two steps seven times to complete a one byte transfer
7. Repeat the previous three steps for any remaining byte transfers
8. Set the SDI pin as an input
9. Deactivate SCS and SYN
10. Enable the SPI module

In case of a precharge command (0xFF), the emulation above is not necessary. Due to the pull-up device on the SDA pin of the STPM10, the processor needs to perform the following steps:

1. Activate SYN first in order to latch the results
2. After at least 1 μ s, activate SCS
3. Write one byte to the transmitter of SPI (this produces 8 pulses on SCL with SDI=1)
4. Deactivate SYN
5. Optionally read the data records (the sequence of reading is altered)
6. Deactivate SCS

7.23 Energy calculation algorithm

Within the STPM10, the computing section of the measured active power uses a completely new patented signal processing approach. This approach allows the device to reach high a level of performance in terms of accuracy.

The signals, coming from the sensors, for the instantaneous voltage are calculated as follows:

Equation 5

$$v(t) = V \cdot \sin \omega t$$

where V is the peak voltage and ω is related to the line frequency.

The instantaneous current is calculated using:

Equation 6

$$i(t) = I \cdot \sin (\omega t + \varphi)$$

where I is the peak current, ω is related to the line frequency and φ is the phase difference between voltage and current.

7.23.1 Active power

In the STPM10, after the pre-conditioning and the A/D conversion, the digital voltage signal (which is dynamically more stable with respect to the current signal) is processed by a differentiator stage which transforms:

Equation 7

$$v(t) \rightarrow v'(t) = dv/dt = V \cdot \omega \cdot \cos \omega t \text{ [see Figure 26 - 5]}$$

the resulting signal, together with the pre-processed and digitalized current signal:

Equation 8

$$i(t) = I \cdot \sin(\omega t + \varphi); \text{ [see Figure 26 - 6]}$$

are then available for the calculation process. These digital signals are also provided to two additional stages, which then integrate of themselves, obtaining:

Equation 9

$$dv/dt \rightarrow v(t) = V \cdot \sin \omega t; \text{ [see Figure 26 - 7]}$$

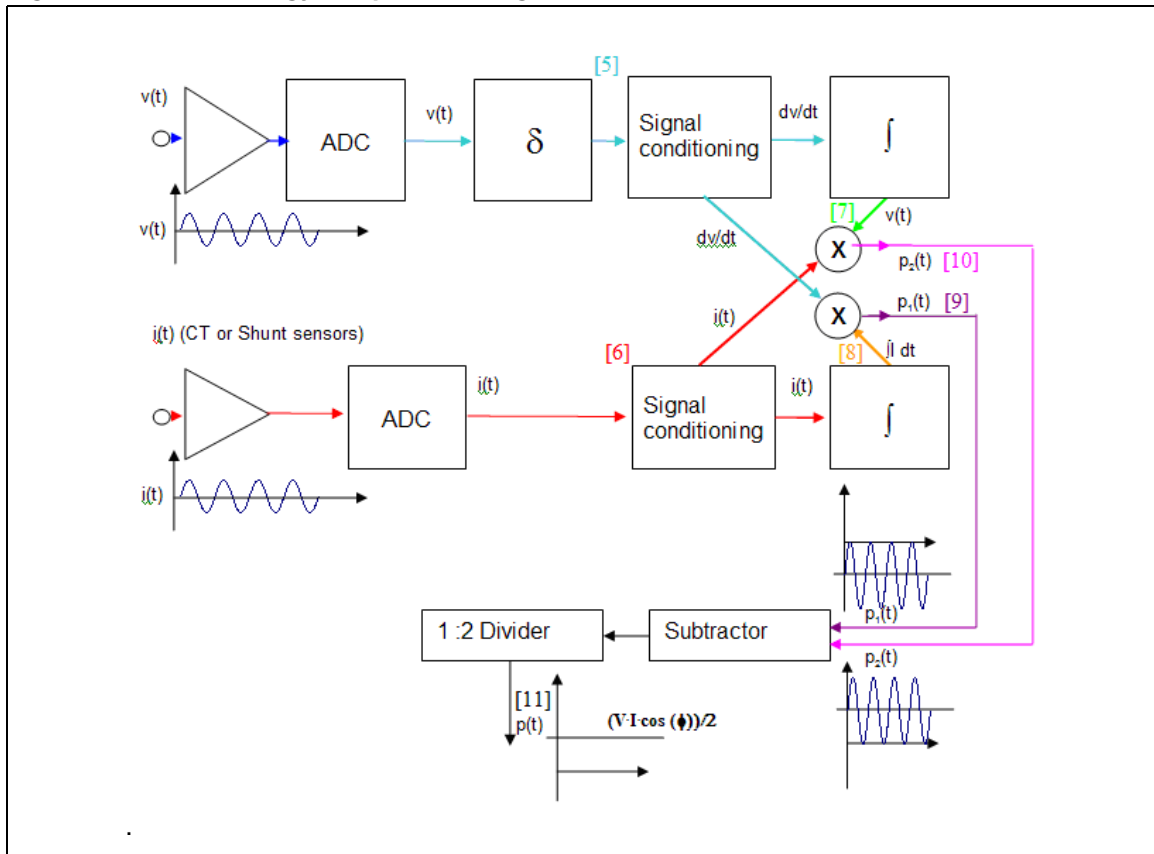

Equation 10

$$i(t) \rightarrow$$

$$I(t) = \int i(t) \cdot dt = -\frac{I}{\omega} \cdot \cos(\omega t + \varphi)$$

[see Figure 26 - 8]

Figure 26. Active energy computation diagram

At this point four signals are available. By combining (pairing) them by means of two multiplying stages, two results are obtained:

Equation 11

$$p_1(t) = \frac{dv}{dt} \cdot \int i(t) \cdot dt = -\frac{V \cdot I \cdot \cos \varphi}{2} - \frac{V \cdot I \cdot \cos(2\omega t + \varphi)}{2}$$

[see [Figure 26 - 9](#)]

Equation 12

$$p_2(t) = v(t) \cdot i(t) = \frac{V \cdot I \cdot \cos \varphi}{2} - \frac{V \cdot I \cdot \cos(2\omega t + \varphi)}{2}$$

[see [Figure 26 - 10](#)]

After these two operations, another stage performs the subtraction between the results p_2 and p_1 and a division by 2, obtaining the active power:

Equation 13

$$p(t) = \frac{(p_2(t) - p_1(t))}{2} = \frac{V \cdot I \cdot \cos \varphi}{2}$$

[see [Figure 26](#) - 11]

In this way, the AC part $V \cdot I \cdot \cos(2\omega t + \varphi)/2$ has been removed from the instantaneous power.

The absence of any AC component allows for a very fast calibration procedure. It requires only the setting of (using the internal device programming registers) the voltage and current sensor conversion constants, using the effective voltage and current (V_{rms} , I_{rms}) readings provided by the device's built-in communication port, avoiding the time-averaged readings of the active power or the need for line synchronization.

7.23.2 Reactive power

The reactive power is produced using the previously-computed signals. In case of shunt sensor the voltage signal is derived while the current signal is not. A first computation is to multiply the DS value of the integrated voltage channel with the value of the integrated current channel, which yields:

Equation 14

$$Q_1(t) = \int v'(t) dt \cdot I(t) = v(t) \cdot I(t) = (V \sin \omega t) \cdot \left(-\frac{I}{\omega} \cos(\omega t + \varphi) \right) = \frac{VI}{2\omega} \cdot (\sin \varphi - \sin(2\omega t + \varphi))$$

The second is to multiply the filtered DS value of the voltage channel with the value of the filtered current channel:

Equation 15

$$Q_2(t) = v'(t) \cdot i(t) = V \omega \cos \omega t \cdot I \sin(\omega t + \varphi) = \frac{VI}{2} \cdot \omega \cdot (\sin \varphi + \sin(2\omega t + \varphi))$$

From the above results, $Q_1(t)$ is proportional to $1/\omega$, while $Q_2(t)$ is proportional to ω . The correct reactive power would result from the following formula:

Equation 16

$$Q = \frac{1}{2} \cdot Q_1(t) \cdot \omega + Q_2(t) \cdot \frac{1}{\omega} = \frac{VI}{2} \sin \varphi$$

Since the above computation would need significant additional circuitry, the reactive power in the STPM10 is calculated using only the $Q_1(t)$ multiplied by ω , which means:

Equation 17

$$Q_3(t) = \frac{1}{2} \cdot Q_1(t) \cdot \omega = \frac{VI}{2} \cdot (\sin \varphi - \sin(2\omega t + \varphi))$$

The reactive power, then, presents a ripple at twice the line frequency. Since the average value of a sinusoid is 0, this ripple does not contribute to the reactive energy calculation over time. Moreover, in the STPM10 the reactive power is not used for meter calibration or to generate the stepper pulses, so this ripple does not affect the overall system performance.

7.23.3 Apparent power and RMS values

The RMS values are calculated starting from the following formulas:

Equation 18

$$\sqrt{\frac{1}{T} \int_0^T I^2(t) dt} = \frac{I}{\omega \cdot \sqrt{2}}$$

Multiplying [Equation 18](#) by ω , the I_{RMS} value is obtained:

Equation 19

$$I_{\text{RMS}} = \frac{I}{\sqrt{2}}$$

The RMS voltage value is obtained by:

Equation 20

$$V_{\text{RMS}} = \sqrt{\frac{1}{T} \int_0^T V^2(t) dt} = \frac{V}{\sqrt{2}}$$

For the apparent power, another value is produced:

Equation 21

$$\sqrt{\frac{1}{T} \int_0^T V^2(t) dt} = \frac{V \cdot \omega}{\sqrt{2}}$$

Multiplying [Equation 18](#) and [Equation 21](#), the apparent power is produced:

Equation 22

$$S = \frac{I}{\omega \cdot \sqrt{2}} \cdot \frac{V \cdot \omega}{\sqrt{2}} = \frac{VI}{2}$$

The DSP then performs the integration of the computed powers into energies. These integrators are implemented as up/down counters and they can roll over. 20-bit output buses of the counters are assigned as the most significant part of the energy data records. It is the responsibility of an application to read the counters at least every second, to avoid missing any rollover.

7.24 STPM10 calibration

Energy meters based on the STPM10 device can be calibrated in a fast and simple way. The calibration is essentially based on the single calibration of the voltage and current channel considering their RMS values rather than on the frequency of the output pulse signal. When the two channels are calibrated, all the other measurements are calibrated too. This allows the calibration to be performed in only one point, thereby shortening the production time of the meter.

This procedure is possible due to the following key factors:

- The device comprises two independent meter channels for line voltage and current, respectively. Each channel includes its own digital calibrator, to adjust the RMS in the range of $\pm 12.5\%$ in 256 steps, and a digital filter, to remove any signal DC component. None of the final results are subject to the calibration procedure because they are achieved from such corrected signals by mathematical modules implemented by hard-wired DSP.
- The device computes different kinds of energies: active, reactive and apparent. The active energy is produced without the 2nd harmonic of the line frequency. It also computes RMS values of measured voltage and current.
- The device produces an energy output pulse signal, but information can also be read through the serial port interface (SPI) and communication channel.
- The device has an embedded memory of 56 bits, used for configuration and calibration purposes. The values of these bits can be read, or they can be changed temporarily through the SPI communication channel.

Let's consider the basic information needed to start the calibration procedure:

Table 13. Working point settings

Parameter		Value
Line RMS voltage	V_n	230 V
Line RMS current	I_n	5 A
Power sensitivity	P	LED: P=128000 pulses/kWh
Shunt sensor	K_S	0.42 mV/A

The typical STPM10 parameters and constants are also known (see [Table 14](#)).

Table 14. Device constants

Parameter		Value	Tolerance
Internal reference voltage	V_{BG}	1.23 V	$\pm 2\%$
Internal calculation frequency	f_M	2^{23} Hz	± 50 ppm
Amplification of voltage ADC	A_V	4	$\pm 1\%$
Amplification of current ADC	A_I	8, 16, 24, 32	$\pm 2\%$
Gain of differentiator	G_{DIF}	0.6135	
Gain of integrator	G_{INT}	0.815	
Gain of decimation filter	G_{DF}	1.004	
RMS voltage record length	B_V	2^{11}	
RMS current record length	B_I	2^{16}	
Constant	D_{UD}	2^{17}	

As shown in [Table 14](#), only analog parameters are the object of calibration because they introduce a certain error. Voltage ADC amplification A_V is constant, while A_I is chosen according to the sensors used.

The calibration algorithm first calculates the voltage divider ratio and, as a final result, the correction parameters, called K_V and K_I , which applied to STPM10 voltage and current measures compensate the small tolerances of the analog components that affect energy calculation.

Since K_V and K_I calibration parameters are the decimal representation of the corresponding configuration bytes CHV and CHP or CHS (respectively, the voltage channel, primary current channel and secondary current channel calibration bytes), at the end of calibration, CHV and CHP or CHS (according to the current channel under calibration, primary or secondary, respectively) the bits' values are obtained.

In the following procedure CHV, CHP and CHS are indicated as C_V and C_I .

Through hard-wired formulas, K_V and K_I tune measured values varying from 0.75 to 1, in 256 steps, according to the value of C_V and C_I (from 0 to 255).

To obtain the greatest correction dynamic, initially calibrators are set in the middle of the range, thus obtaining a calibration range of 12.5% per voltage or current channel:

Calibrator value

$$K_V = K_I = 0.875$$

$$C_I = C_V = 128$$

In this way, it is possible to tune K_V and K_I to obtain a precise measurement: for example $C_V = 0$ generates a correction factor of -12.5% ($K_V = 0.75$) and $C_V = 255$ determines a correction factor of +12.5% ($K_V = 1$), and so on.

Based on the above, the following formulas relating to $K_{V,i}$ and $C_{V,i}$ are obtained:

$$K_{V,i} = (C_{V,i} / 128) * 0.125 + 0.75$$

$$C_{V,i} = 1024 * K_{V,i} - 768$$

The calibration procedure outputs C_V and C_I values, which allow the above power sensitivity of the meter.

This sensitivity is used to calculate target frequency at the LED pin for nominal voltage and current values:

$$X_F = f * 64$$

with:

$$f = PM * I_n * V_n / 3600000$$

From the values above and for both chosen amplification factor $A_I = 32$ and initial calibration data, the following target values can be calculated:

Target RMS reading for a given I_n :

$$X_I = I_n * K_S * A_I * K_I * G_{INT} * G_{DF} * G_{DIF} * B_I / (V_{BG} * 1000) = 1573$$

Target RMS reading for a given V_n :

$$X_V = f * B_V * B_I * D_{UD} / (f_M * X_I) = 852$$

The output of the voltage divider is then:

$$V_{DIV} = (X_V * V_{BG}) / (2 * G_{DIF} * A_V * K_V * G_{DF} * G_{INT} * B_V) = 145.6 \text{ mV}$$

Choosing $R_2 = 500 \Omega$ (connected between V_I and V_{SS}), the R_1 resistor (connected between V_{LINE} and V_{IP}) value is obtained:

$$R_1 = R_2 * (V_n - V_{DIV}) / V_{DIV} = 789.3 \Omega$$

Indicating, with I_A and V_A , the real readings on the STPM10 RMS voltage and current registers, and with X_I and X_V ideal values of RMS current and voltage readings already calculated, the final values for calibrators can be calculated as:

$$X_V = (K_V * V_A) / 0.875$$

$$X_I = (K_I * I_A) / 0.875$$

If the computed final calibration data would fall out of the calibration data range, the energy meter should be recognized as bad, or the given presumptions and calculations above should be checked. Otherwise, if the final data of the calibrators would be written into the energy meter, the RMS readings should be very close to the target values I and V , and the frequency of the LED output should be very close to the target value f .

8 Application design

The choice of the external components in the transduction section of the application is a crucial point in the application design, affecting the precision and the resolution of the whole system.

Among the several considerations, a compromise has to be found between the following needs:

1. Maximize the signal to noise ratio in the voltage channel,
2. Choose the current to voltage conversion ratio K_s and the voltage divider ratio in a way that calibration can be achieved (please refer to AN2299)
3. Choose K_s to take advantage of the whole current dynamic range according to desired maximum current and resolution.

To maximize the signal to noise ratio of the current channel the voltage divider resistors ratio should be as close as possible to those shown in [Table 15](#).

Table 15. Resistor divider ratio

Function	Component	Parameter	Value	Unit
Line voltage interface	Resistor divider	R to R ratio $V_{RMS}=230V$	1650	V/V
		R to R ratio $V_{RMS}=110V$	830	

The [Figure 27](#) below shows a reference schematic for an application with the following properties:

- $P = 64000 \text{ imp/kWh}$
- $I_{NOM} = 5 \text{ A}$
- $I_{MAX} = 60 \text{ A}$.

Typical values for the current sensors sensitivity, also used in the reference schematic below, are shown in [Table 16](#).

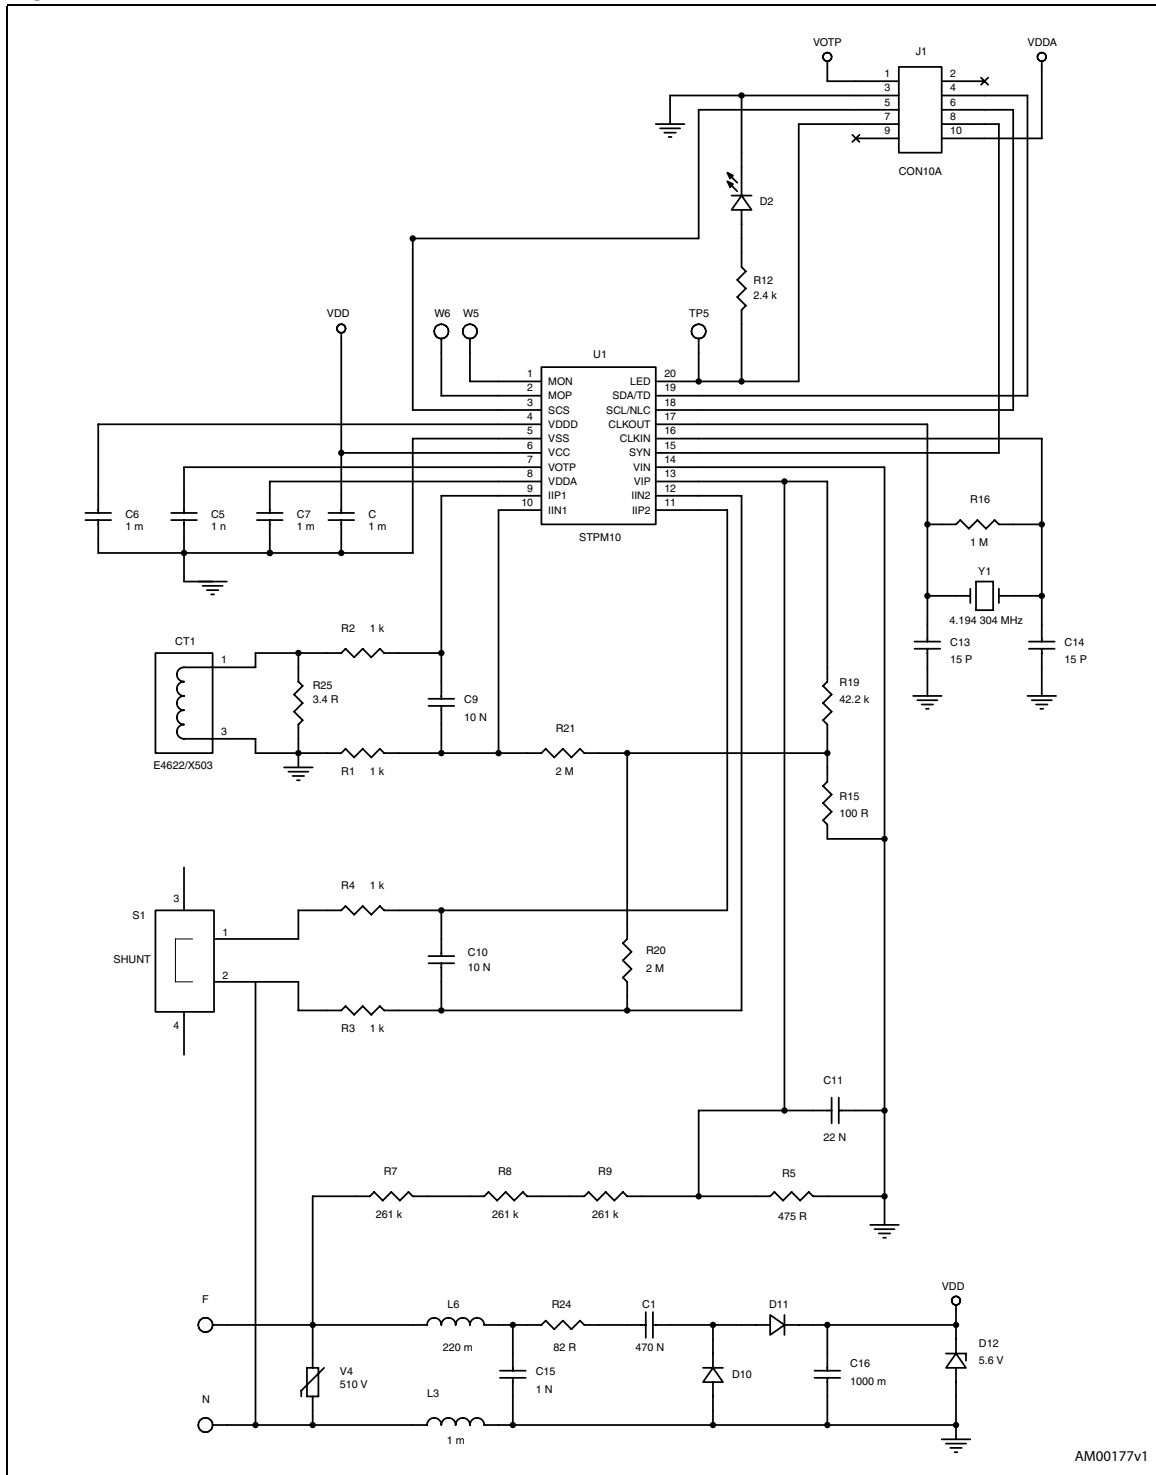

Table 16. Current channel typical components

Function	Component	Parameter	Value	Unit
Line current interface	Current shunt	Current to voltage conversion ratio K_s	0.425	mV/A
	Current transformer		1.7	
	Rogowsky coil		0.13	

Note: If the device is used in configuration $PST = 1$, $TMP = 1$ (primary channel with CT, secondary channel with Shunt), the shunt K_s must always be equal to one fourth of the current transformer K_s .

Additional considerations on the application design, suggestions for noise and crosstalk reduction can be found in the AN2317.
