# CMOS Video Speed, 8-Bit, 50 MSPS, R2R D/A Converters 

## Features

- CMOS/SOS Low Power
- R2R Output, Segmented for Low "Glitch"
- CMOS/TTL Compatible Inputs
- Fast Settling: (Typ) to $1 / 2$ LSB 20ns
- Feedthrough Latch for Clocked or Unclocked Use
- Accuracy (Typ). $\pm 0.5$ LSB
- Data Complement Control
- High Update Rate (Typ) 50 MHz
- Unipolar or Bipolar Operation

## Applications

- TV/Video Display
- High Speed Oscilloscope Display
- Digital Waveform Generator
- Direct Digital Synthesis

## Description

The CA3338 family are CMOS/SOS high speed R2R voltage output digital-to-analog converters. They can operate from a single +5 V supply, at video speeds, and can produce "rail-to-rail" output swings. Internal level shifters and a pin for an optional second supply provide for an output range below digital ground. The data complement control allows the inversion of input data while the latch enable control provides either feedthrough or latched operation. Both ends of the R2R ladder network are available externally and may be modulated for gain or offset adjustments. In addition, "glitch" energy has been kept very low by segmenting and thermometer encoding of the upper 3 bits.
The CA3338 is manufactured on a sapphire substrate to give low dynamic power dissipation, low output capacitance, and inherent latch-up resistance.

Pin Descriptions

| PIN | NAME | DESCRIPTION |
| :---: | :---: | :---: |
| 1 | D7 | Most Significant Bit |
| 2 | D6 | Input |
| 3 | D5 | Data |
| 4 | D4 | Bits |
| 5 | D3 | $($ High $=$ True $)$ |
| 6 | D2 |  |
| 7 | D1 |  |
| 8 | VSS | Digital Ground |
| 9 | $\mathrm{D}_{0}$ | Least Significant Bit. Input Data Bit |
| 10 | $\mathrm{V}_{\mathrm{EE}}$ | Analog Ground |
| 11 | $\mathrm{V}_{\text {REF }}{ }^{-}$ | Reference Voltage Negative Input |
| 12 | VOUT | Analog Output |
| 13 | $\mathrm{V}_{\text {REF }}+$ | Reference Voltage Positive Input |
| 14 | COMP | Data Complement Control input. Active High |
| 15 | LE | Latch Enable Input. Active Low |
| 16 | $\mathrm{V}_{\mathrm{DD}}$ | Digital Power Supply, +5V |

## Digital Signal Path

The digital inputs (LE, COMP, and DO - D7) are of TTL compatible HCT High Speed CMOS design: the loading is essentially capacitive and the logic threshold is typically 1.5 V .

The 8 data bits, D0 (weighted $2^{0}$ ) through D7 (weighted $2^{7}$ ), are applied to Exclusive OR gates (see Functional Diagram). The COMP (data complement) control provides the second input to the gates: if COMP is high, the data bits will be inverted as they pass through.

The input data and the LE (latch enable) signals are next applied to a level shifter. The inputs, operating between the levels of $\mathrm{V}_{\mathrm{DD}}$ and $\mathrm{V}_{\mathrm{SS}}$, are shifted to operate between $\mathrm{V}_{\mathrm{DD}}$ and $\mathrm{V}_{\mathrm{EE}}$. $\mathrm{V}_{\mathrm{EE}}$ optionally at ground or at a negative voltage, will be discussed under bipolar operation. All further logic elements except the output drivers operate from the $\mathrm{V}_{\mathrm{DD}}$ and $\mathrm{V}_{\mathrm{EE}}$ supplies.
The upper 3 bits of data, D5 through D7, are input to a 3-to-7 line bar graph encoder. The encoder outputs and D0 through D4 are applied to a feedthrough latch, which is controlled by LE (latch enable).

FIGURE 1. DATA TO LATCH ENABLE TIMING

FIGURE 2. DATA AND LATCH ENABLE TO OUTPUT TIMING

## Latch Operation

Data is fed from input to output while LE is low: LE should be tied low for non-clocked operation.

Non-clocked operation or changing data while LE is low is not recommended for applications requiring low output "glitch" energy: there is no guarantee of the simultaneous changing of input data or the equal propagation delay of all bits through the converter. Several parameters are given if the converter is to be used in either of these modes: $t_{D 2}$ gives the delay from the input changing to the output changing ( $10 \%$ ), while $\mathrm{t}_{\mathrm{SU} 2}$ and $\mathrm{t}_{\mathrm{H}}$ give the set up and hold times (referred to LE rising edge) needed to latch data. See Figures 1 and 2.

Clocked operation is needed for low "glitch" energy use. Data must meet the given $\mathrm{t}_{\mathrm{SU}}$, set up time to the LE falling edge, and the $t_{H}$ hold time from the $L E$ rising edge. The delay to the output changing, $\mathrm{t}_{\mathrm{D} 1}$, is now referred to the LE falling edge.

There is no need for a square wave LE clock; LE must only meet the minimum tw pulse width for successful latch operation. Generally, output timing (desired accuracy of settling) sets the upper limit of usable clock frequency.

## Output Structure

The latches feed data to a row of high current CMOS drivers, which in turn feed a modified R2R ladder network.

The " N " channel (pull down) transistor of each driver plus the bottom " 2 R " resistor are returned to $\mathrm{V}_{\mathrm{REF}}$ - this is the (-) fullscale reference. The "P" channel (pull up) transistor of each driver is returned to $\mathrm{V}_{\text {REF }}{ }^{+}$, the (+) full-scale reference.

In unipolar operation, $\mathrm{V}_{\text {REF- }}$ would typically be returned to analog ground, but may be raised above ground (see specifications). There is substantial code dependent current that flows from $\mathrm{V}_{\text {REF }}+$ to $\mathrm{V}_{\text {REF }}{ }^{-}$(see $\mathrm{V}_{\text {REF }}+$ input current in specifications), so $\mathrm{V}_{\text {REF }}$ - should have a low impedance path to ground.

In bipolar operation, $\mathrm{V}_{\text {REF }}$ - would be returned to a negative voltage (the maximum voltage rating to $\mathrm{V}_{\mathrm{DD}}$ must be observed). $\mathrm{V}_{\mathrm{EE}}$, which supplies the gate potential for the output drivers, must be returned to a point at least as negative as $\mathrm{V}_{\mathrm{REF}}{ }^{-}$. Note that the maximum clocking speed decreases when the bipolar mode is used.

## Static Characteristics

The ideal 8-bit $\mathrm{D} / \mathrm{A}$ would have an output equal to $\mathrm{V}_{\text {REF }}$ - with an input code of 00 HEX (zero scale output), and an output equal to $255 / 256$ of $\mathrm{V}_{\text {REF }}$ (referred to $\mathrm{V}_{\text {REF }}$ ) with an input code of $\mathrm{FF}_{\text {HEX }}$ (full scale output). The difference between the ideal and actual values of these two parameters are the OFFSET and GAIN errors, respectively; see Figure 3.

If the code into an 8 -bit $D / A$ is changed by 1 count, the output should change by $1 / 255$ (full scale output - zero scale output). A deviation from this step size is a differential linearity error, see Figure 4. Note that the error is expressed in fractions of the ideal step size (usually called an LSB). Also note that if the (-) differential linearity error is less (in absolute numbers) than 1 LSB, the device is monotonic. (The output will always increase for increasing code or decrease for decreasing code).
If the code into an 8 -bit D/A is at any value, say "N", the output voltage should be $\mathrm{N} / 255$ of the full scale output (referred to the zero scale output). Any deviation from that output is an integral linearity error, usually expressed in LSBs. See Figure 4.
Note that OFFSET and GAIN errors do not affect integral linearity, as the linearity is referenced to actual zero and full scale outputs, not ideal. Absolute accuracy would have to also take these errors into account.

FIGURE 3. D/A OFFSET AND GAIN ERROR

FIGURE 4. D/A INTEGRAL AND DIFFERENTIAL LINEARITY ERROR

## Dynamic Characteristics

Keeping the full-scale range ( $\mathrm{V}_{\text {REF }}{ }^{-}-\mathrm{V}_{\mathrm{REF}}{ }^{-}$) as high as possible gives the best linearity and lowest "glitch" energy (referred to 1 V ). This provides the best " P " and " N " channel gate drives (hence saturation resistance) and propagation
delays. The $\mathrm{V}_{\text {REF }}+$ (and $\mathrm{V}_{\text {REF }}$ - if bipolar) terminal should be well bypassed as near the chip as possible.
"Glitch" energy is defined as a spurious voltage that occurs as the output is changed from one voltage to another. In a binary input converter, it is usually highest at the most significant bit transition ( $7 \mathrm{~F}_{\text {HEX }}$ to 80 HEX for an 8 bit device), and can be measured by displaying the output as the input code alternates around that point. The "glitch" energy is the area between the actual output display and an ideal one LSB step voltage (subtracting negative area from positive), at either the positive or negative-going step. It is usually expressed in $\mathrm{pV} / \mathrm{s}$.
The CA3338 uses a modified R2R ladder, where the 3 most significant bits drive a bar graph decoder and 7 equally weighted resistors. This makes the "glitch" energy at each $1 / 8$ scale transition ( $1 \mathrm{~F}_{\text {HEX }}$ to $20_{\mathrm{HEX}}, 3 \mathrm{~F}_{\mathrm{HEX}}$ to $40_{\mathrm{HEX}}$, etc.) essentially equal, and far less than the MSB transition would otherwise display.

For the purpose of comparison to other converters, the output should be resistively divided to 1V full scale. Figure 5 shows a typical hook-up for checking "glitch" energy or settling time.
The settling time of the A/D is mainly a function of the output resistance (approximately $160 \Omega$ in parallel with the load resistance) and the load plus internal chip capacitance. Both "glitch" energy and settling time measurements require very good circuit and probe grounding: a probe tip connector such as Tektronix part number 131-0258-00 is recommended.

NOTES:
2. $\mathrm{V}_{\mathrm{OUT}(\mathrm{P}-\mathrm{P})}$ is approximate, and will vary as ROUT of $\mathrm{D} / \mathrm{A}$ varies.
3. All drawn capacitors are $0.1 \mu \mathrm{~F}$ multilayer ceramic $/ 4.7 \mu \mathrm{~F}$ tantalum.
4. Dashed connections are for unipolar operation. Solid connection are for bipolar operation.

## Applications

The output of the CA3338 can be resistively divided to match a doubly terminated $50 \Omega$ or $75 \Omega$ line, although peak-to-peak swings of less than 1 V may result. The output magnitude will also vary with the converter's output impedance. Figure 5 shows such an application. Note that because of the HCT input structure, the CA3338 could be operated up to $+7.5 \mathrm{~V} \mathrm{~V}_{\mathrm{DD}}$ and $\mathrm{V}_{\text {REF }}+$ supplies and still accept 0 V to 5 V CMOS input voltages.

If larger voltage swings or better accuracy is desired, a high speed output buffer, such as the HA-5033, HA-2542, or CA3450, can be employed. Figure 6 shows a typical application, with the output capable of driving $\pm 2 \mathrm{~V}$ into multiple $50 \Omega$ terminated lines.

## Operating and Handling Considerations

## HANDLING

All inputs and outputs of CMOS devices have a network for electrostatic protection during handling. Recommended handling practices for CMOS devices are described in AN6525. "Guide to Better Handling and Operation of CMOS Integrated Circuits."

## OPERATING

## Operating Voltage

During operation near the maximum supply voltage limit, care should be taken to avoid or suppress power supply turn-on and turn-off transients, power supply ripple, or ground noise; any of these conditions must not cause the absolute maximum ratings to be exceeded.

## Input Signals

To prevent damage to the input protection circuit, input signals should never be greater than $\mathrm{V}_{\mathrm{DD}}$ nor less than $\mathrm{V}_{\text {SS }}$. Input currents must not exceed 20 mA even when the power supply is off.

## Unused Inputs

A connection must be provided at every input terminal. All unused input terminals must be connected to either $\mathrm{V}_{\mathrm{CC}}$ or GND, whichever is appropriate.
